The Problem Formulation

1. This is the 5th report on the theme, so I shall concentrate only

on the new problems and findings. There are three clusters of them:

a) Existence of the leverage values corresponding to safe debt and sound money;

 b) Exploring differences between micro- and macro-debt.
 Transformation of debt redemption into its safe refinancing and rolling over;

c) Deleveraging as an empirical process and its modelling.

2. Basic Definitions

Debt is a contractual obligation, or a"promise" of future payments;

Debt is reimbursed with money, and lenders deserve to be compensated at the face value of their loans;

The problem of money collateralization. The real bills doctrine of *J. Law* and *A. Smith*; The sound money definition, M(t)/E(t) = 1;

Macrofinancial balance and ratios

3. The standard macro-balance of financial assets and liabilities.

No global bankruptcies are allowed, but crises of liquidity are possible Empirical balances are treated for the fixed time-to-maturity

parameter T; the actual time $0 < t \le T$

A(t,T) = [M(t) + B(t,T)] + E(t) = D(t,T) + E(t)

In terms of leverage assuming that money is sound, M(t)/E(t) = 1:

$$B_{T}(t) / E(t) = l(t) - 2$$
 or $D_{T}(t) = l(t) - 1$

{Sources: World Bank, Institute of International Finance, Author's estimations}

Zero-coupon riskless macro-bond

4. The basic "building block" of the fixed-income finance is a pure riskless zero-coupon bond:

 $B(t,T)\exp[y(t,T)(T-t)] = M(T); \ 0 \le t \le T$

where B(t,T) is the debt contractual obligation; y(t,T) is the spot interest rate (yield-to-maturity); $M(T,T) = M_B(T)$ is the debt principal or its "promised" money equivalent at t = T.

The stylized debt reimbursement

5. The stylized process of the macro-debt reimbursement

 $Lim_{T \to t} B(t,T) = B(t,t) \equiv M_B(t)$

where $M_B(t)$ is the money equivalent of a loan. Hence money is a debt which is repaid instantaneously.

Banknote, digital money. Money is an instantaneous debt.

The actual process of the macro-debt reimbursement is a financial crisis hence it is a highly undesirable event.

Rates of return in the fixed-income finance

6. a) the spot interest rate: y(t,T) = -ln B(t,T)/(T-t);
b) the forward rate of return: f(t,T) = -∂ln B(t,T)/∂T;
c) the instantaneous rate of return: r(t) = y(t,t) = -∂ln B(t,t)/∂t;
is a price of ultra-short credit like EONIA, SONIA, RUONIA

- d) "Money does not beget money" (Aristotle):
- $B(t,t) \exp[y(t,t)(t-t)] = B(t,t); 0 < t \le T$

{Ineffectiveness of monetary stimuli within the QE policy}

The existence of critical leverage values

7. There exist leverage values at which the debt is fully reimbursed with sound money:

$$\begin{split} l(t) &= 2; \ B_T(t) / E(t) = 0 \Rightarrow B_T(t) = 0 \approx D_T = M_B(t); \\ l(t) &= 3; \ B_T(t) / E(t) = 1 \Rightarrow B_T(t) = E(t) \approx B_T(t) = \hat{M}(t) = E(t); \\ Hence \quad 2 \le l \le 3 \end{split}$$

Feasibility: lower boundary

8. The feasibility of leverage values located in the above the interval. The lower boundary is the (nontrivial) solution to the well-known equation: l = l/(l-1) or $l^2 - 2l = 0$.

The upper boundary could be reformulated in terms of the long run no-arbitrage relations between aggregates of borrowers and creditors.

Leverage and the Collateral Ratio

The balanced financial market condition

9. Macrofinancial balances of levels and flows

A(t) = D(t) + E(t) and dA(t) = dD(t) + dE(t)

are equivalently represented by their convolution:

$$\mu l(t) = r(l-1) + \rho$$

where $\mu \equiv ROA$; $\rho \equiv ROE$; $r = r_s = r_L$. It is the balanced financial market, BFM, condition which is always true in the short run. In the model financial spreads are subject to c/a = a/b where parameter $b = a^2/c$.

Some global rates of return in 1999-2017

The anchor leverage

10. Natura abhorret vacuum. In the long run aggregates of borrowers and creditors are mutually adjusted so as

$$\rho^{e}(l) = r + (\mu - r)l;$$

 $\mu^{e}(l) = r + (\rho - r)l^{-1}$ and $\rho^{e}(l) = \mu^{e}(l)$ or $l^{2} - a/b = 0.$

The root of the latter defines the anchor leverage $l_N = (a/b)^{0.5}$.

The safe debt reimbursement in the long run

11. If the macro-debt is reimbursed in the long run then

$$l^2 - 2l = l^2 - a / b$$

with the positive root $\hat{l} = a/2b$. If $\hat{l} \cong 3$ the safe debt interval is

$$2 \le l_N \le a / 2b$$

The logistic leverage dynamic

12. The leverage deterministic dynamic is

$$dl(t) = l(t)[a - bl(t)]dt; l(0) = l_0$$

with solution: $l(t) = K\{1 + (\frac{K}{l_0} - 1) \exp[-at]\}^{-1}$

where K = a / b is the nontrivial steady state of the logistic equation. The transition (the pass-through) function:

$$f(l) = al - bl^2$$

measures the debt refinancing and its ability to be rolled over. Its maximum takes place at $\hat{l} = a/2b$ where money is sound:

$$f'(l) = a - 2bl = 0.$$

The logistic leverage trajectories

The micro- vs macro-debt

13. Now, the second strand of the study: micro- vs macro-debt.

Any particular micro-debt has to be repaid in the finite time. It is safe, by definition, being paid off in full. {Russian rates for "non-callable credits" in 90ties were in vogue due to disordered economic transition}

Contrary to that, the macro-debt is a perpetual aggregate of promises; separate tranches have to be repaid, and their simultaneous reimbursement is tantamount to a financial crisis.

The proof of the macro-debt safety is in its ability to be refinanced and rolled over. If every market participant is convinced in the safety of her/his money the debt as a whole is safely rolled over.

The self-negation mechanism

14. The mechanism of self-negation: when everybody knows that her/his money is callable on short notice nobody would claim it back without particular personal reasons.

Debt reimbursement is transformed into its safe rolling over at the leverage value $\hat{l} = a/2b$.

Thus, the problem seems to be solved; it is, but not completely because the macrofinancial system is unstable (semi-stable) at the safe debt roll-over point.

The self-negation mechanism

15. Let us return to the empirical data in 1999-2017. The asset/equity elasticity in 1999-2017 is 1.25, but the leverage process is very different: it is, in fact, a process of deleveraging.

16. Deleveraging: debts outstanding are netted and compressed;{mutual indebtness offsetting in the Soviet economy, and a lucrative multibillion business now, especially on markets of derivatives}

central banks purchases of large chunks of public debt; {BoJ holds 43 percent of government debt);

world equity markets tend to be overvaluated for many years {August, 2019 correction and the YC inversion on the major markets}

Two phases of deleveraging in 1999-2017

The process of deleveraging

17. The standard logistic equation is modified into the following model:

 $dl(t) = [(a - \delta)l(t) - bl^{2}(t)]dt$

with pass-through function: $f(l,\delta) = al - bl^2 - \delta l$, and stable steady state $K(\delta) = K(1 - \delta / a)$.

The maximal effect of deleveraging, $\max_{\delta} [\delta K(\delta)]$ takes place at $\hat{\delta} = 0.5a$, that is, precisely, at the safe debt roll-over point, $\hat{l} = a/2b$.

The solution of $K_{17}(\delta) = K_{12}(1 - \delta / a)$ defines

 $a_{17} = 0.0029$; $\delta = 0.0004$ hence the prolong and uncertain travel between different steady states.

Deleveraging in 2002-2007 reconstruction

The global leverage regression

The stochastic logistic diffusion

18. The new factor governing the process appears in the logistic stochastic diffusion:

 $dl(t) = l(t)[a - bl(t)]dt + \sigma l(t)dZ(t)$

where $\sigma = 0.16$ is the empirical volatility; and $Z(t) = \int_{0}^{t} dZ(u)$ is

a standard Brownian motion with independent and self-similar (the Hurst exponent, H = 0.5) increments dZ(t).

Parameter *a* was used *per se* or including the deleveraging intensity δ .

Due to high empirical volatility, $\sigma = 0.16$, the future leverage realizations dramatically decreased: from $l_{17} = 4.14$ to $l^* = 0.416$, that is, to values smaller than one.

11/28/2019

Realizations of stochastic leverage

A random leverage equivalent representations

19. It is known that a random process x(t) with coefficients of drift and noise given by the general Ito processes P[x(t), t] and

 $\sqrt{Q[x(t),t]}$ can be equivalently represented either by its SDE:

$$dx(t) = P[x(t),t]dt + \sqrt{Q[x(t),t]}dZ(t),$$

or by the Kolmogorov-Fokker-Plank equation:

$$\frac{\partial}{\partial t} p[x(t), t] = -\frac{\partial}{\partial l} \{ P[x(t), y] p[l(t), t] \} + \frac{1}{2} \frac{\partial^2}{\partial l^2} \{ Q[x(t), t] p[x(t), t] \}$$

where p[x(t), t] is the "transition" probability density function.

Boundaries and initial conditions of the KPF equation are specified by the actual process under consideration.

The KFP stationary equation and its solution

20. A non-trivial solution to the ordinary differential KFP equation:

$$-\frac{d}{dl}[l(a-bl)p(l)] + \frac{1}{2}\frac{d^2}{dl^2}[\sigma^2 l^2 p(l)] = 0$$

is the stationary pdf, p(l), of a random leverage process

$$p(l;\alpha,\beta) = [\beta^{\alpha} / \Gamma(\alpha)] l^{\alpha-1} \exp[-\beta l].$$

It defines the gamma distribution with parameters $\alpha = (2a/\sigma^2) - 1$

and $\beta = 2b/\sigma^2$ (the parameter of scale 1/ β is used in *Mathematica 10*).

The normalization constant $\beta^{\alpha} / \Gamma(\alpha)$ is found from a gamma function:

$$\Gamma(\alpha) = \int_0^\infty x^{\alpha - 1} \exp[-x] dx.$$

Figure IX Three forms of a gamma distribution

Moments of the stationary gamma distribution

22. The PDF of a gamma distribution is skewed to the right and its expectation:

$$\langle L \rangle = \frac{\alpha}{\beta} = K - \frac{\sigma^2}{2b}$$

is larger than its mode (the most probable long-term leverage):

$$Mo = \frac{\alpha - 1}{\beta} = K - \frac{\sigma^2}{b}; \ \alpha \ge 1.$$

The random leverage convergence criterion

23. If the mode is the same as the anchor leverage l_N the above formula could be transformed into:

$$(a/b)^{0.5} = (a - \sigma_N^2)/b$$
 or $a/2b = (a - \sigma_N^2)/b$

where σ_N^2 is the implied variance of the gamma distributed stationary leverage. It is an indicator of the long-term default risk. For the positive parameters $\{a, b\}$ the implied variance σ_N^2 :

$$\sigma_N^2 = a - \sqrt{ab} \quad \text{or} \quad \sigma_N^2 = 0.5 a \,.$$

The long-term leverage scenarios

Conclusions

24. The global leverage evolution is modelled as a generalized process of parametric deleveraging; the safe debt is rolled-over within particular interval of leverage values.

The model outlined alternatives: either deleveraging is kept under control and debt is safely accumulated, or devastating consequences of a bursting equity bubble are inevitable. Without excessive global equity valuation the first alternative is realized at $\hat{\delta} = 0.5a$; its stochastic analogue $\sigma_N^2 \le 0.5a$ provides convergence to the unimodal gamma distribution.

The sustained deleveraging could be accomplished due to coordinated efforts of financial regulators and central banks.
