Table of Contents

- 8 Welcome to the 6th HBP Student Conference on Interdisciplinary Brain Research**
- 10 Preface**
- 11 I Brain atlases & clinical neuroscience**
- 11 Mohamed Baghdad, Niamh Brady, Irene Costantini, Giacomo Mazzamuto, Marina Scardigli, Filippo Castelli, Ludovico Silvestri, Francesco Saverio Pavone:** Reconstructing the Broca's area of the human brain using a customized dual-view light sheet for optimized imaging time and improved resolution
- 15 Helena M. Ferreira, Ana Catarina Sousa, Hugo Ferreira, Sofia Santos, José Sereno, João Martins, Miguel Castelo-Branco, Joana Gonçalves:** Sex-dependent cortical excitatory/inhibitory imbalance is associated with behaviour alterations in a mouse model of autism spectrum disorder
- 17 Dimitrios Georgiou, Christina Emmanouil, Georgios Vlachos, Leonidas Stefanis, Ioannis Michalopoulos:** Study on the effects of various risk factors on the onset of Parkinson's disease using machine and deep learning
- 22 Marina Ivanova, Zheng Gong, Thomas Hein, Maria Herrojo Ruiz, Vadim Nikulin:** Heart-brain interactions in anxiety influence decision-making and learning
- 26 Viktoriya Manyukhina, Andrey Prokofyev, Tatiana Obukhova, Tatiana Stroganova, Elena Orekhova:** Visual gamma oscillations and perceptual spatial suppression point to impaired neural inhibition in premenstrual dysphoric disorder

- 30 Beatriz Martins, Miguel Castelo Branco, Joana Gonçalves, and João Martins:** Characterization of microbiome and brain NPY system alterations in a mouse model of autism spectrum disorder
- 32 Svitlana Oleshko, Francesc Fernández-Albert, Matthias Heinig, Sergio Picart-Armada, Annalisa Marsico:** Integration of multi-omics data using graph neural networks to identify and contextualize biomarker genes for psychiatric disorders
- 36 M. Lapo Pais, J. Martins, M. Castelo-Branco, J. Gonçalves:** *Tsc2^{+/-}* mouse model: Probing clinical manifestation of epilepsy in Tuberous Sclerosis Complex
- 40 II Brain simulation & brain inspired architectures**
- 40 Chiara De Luca, Leonardo Tonielli, Bruno Golosio, Gianmarco Tiddia, Irene Bernava, Cristiano Capone, Davide Cipollini, Giulia De Bonis, Cosimo Lupo, Elena Pastorelli, Francesco Simula, Pier Stanislao Paolucci:** Incremental awake-NREM-REM learning cycles: Cognitive and energetic effects in a multi-area thalamo-cortical spiking model
- 45 Roberta M. Lorenzi, Alice Geminiani, Claudia A.M. Gandini Wheeler-Kingshott, Fulvia Palesi, Claudia Casellato, Egidio D'Angelo:** GRL MF: Mean field model of the cerebellar granular layer
- 51 Ruxandra Barbulescu, Gonçalo Mestre, Arlindo L. Oliveira, L. Miguel Silveira:** Modelling the dynamic behaviour of the *C. elegans* nervous system with machine learning techniques
- 56 Panfilova, E.A., Burlakov E.O., Verkhlyutov, V.M:** Traveling waves in the resting state are initiated by the connectome

- 60 Francisco P. dos Santos, Sonia Hassissene, Paul F.M.J. Verschure:** Role of excitatory-inhibitory homeostasis in the recovery of functional network properties after focal lesion: A computational account
- 65 Lea Steffen, Philipp Augenstein, Stefan Ulbrich, Arne Rönnau, Rüdiger Dillmann:** Configuration aware neural path: Planning in the task space
- 70 Márton Szép, Leander Lauenburg, Kevin Farkas, Xiyang Su, Chuanlong Zang, Mahmoud Akl, Florian Walter, Josip Josifovski, Alois Knoll:** Solving robotic reaching tasks in the neurorobotics platform with reinforcement learning
- 75 J. Camilo Vasquez Tieck, Daniel Azanov, Jacques Kaiser, Rüdiger Dillmann:** Perception-driven control of multiple robotic arms in the Neurorobotics Platform
- 79 Michiel van der Vlag, Marmaduke Woodman, Jan Fousek, Sandra Diaz-Pier, Aaron Perez Martin, Viktor Jirsa, Abigail Morrison:** RateML: A code generation tool for BrainNetwork models
- 85 Ben von Hünenbein, Ismael Jaras, Laura Kriener, Jakob Jordan, Walter Senn, Mihai A. Petrovici:** Towards fully embedded biologically inspired deep learning on neuromorphic hardware
- 90 III Brain organisation & theoretical neuroscience**
- 90 Peter Bouss, Alessandra Stella, Günther Palm, Sonja Grün:** Surrogate techniques to evaluate significance of spike patterns
- 95 Raquel Marques, Diana Tavares, António Marques, Pedro Monteiro, António Correia:** Electroencephalographic and behavioural evaluation of visual attention capacity in deaf individuals

- 100 Nikita Otstavnov, Nieto Doval Carlos Murielo, Stanislav Otstavnov, Matteo Feurra:** Investigation of frontoparietal involvement to working memory functioning by transcranial direct current stimulation
- 105 Sergio Plaza-Alonso, Nicolás Cano-Astorga, Javier DeFelipe, Lidia Alonso-Nanclares:** Focused Ion Beam/Scanning electron microscopy on the study of the human entorhinal cortex
- 111 Meghana Gayatri Potta, Pau Vilimelis Aceituno, Benjamin F. Grewe:** Does backpropagation yield the underlying solution used by the brain?
- 115 Alexis Thual, Bertrand Thirion, Stanislas Dehaene:** Deep phenotyping to build inter-subject alignments using optimal transport
- 119 Nestor Timonidis, Rembrandt Bakker, Maria Carla Piastra, Maria Garcia-Amado, Mario Rubio, Francisco Clasca, Paul Tiesinga:** Finding order in thousands of fully reconstructed long-range projection neurons in the mouse brain
- 123 IV Systems & cognitive neuroscience**
- 123 Aleksandra Dolgoarshinnaia, Beatriz Martín-Luengo:** Reality monitoring in native and foreign language
- 128 Sandra Doval, Pablo Cuesta, Ricardo Bruña, Lucía Torres Simón, Brenda Chino, Inés Abalo Rodríguez, Fernando Maestú, David López-Sanz:** Diachronic changes in oscillatory activity and its cortical generators in non-pathological development measured by MEG
- 134 Claudia Sigrid Hofmann, Sonja Rossi:** Emotional prosody processing in trans women

- 139 Elizaveta Ivanova, Beatriz Martín-Luengo:** Prospective metamemory monitoring: Source vs item
- 144 Mica Komarnyckyj, Chris Retzler, Zhipeng Cao, Giorgio Ganis, Anna Murphy, Robert Whelan, Elsa Fouragnan:** At-risk alcohol users have disrupted valence discrimination during reward anticipation
- 148 Valentina Pergher, Marc M. Van Hulle:** Effect of stimulus category on fast perceptual learning evidenced with ERP and behavioural responses
- 152 Ashrafur Rahman, Mahadi Hassan Fahim, Shakil Ahmed, Mehedi Hasan Apu, Arif Anzum Shuvo, Rehnuma Tabassum Jhalak, Kazi Nishat Tasnim, Khadiza Sharmin Lopa:** M1 muscarinic acetylcholine receptor improves the memory in D-galactose induced ageing mice model
- 157 Cristian Reyes, Iván Padrón, Sara Nila Yagual, Hipólito Marrero:** The effect of tDCS on the rSTS on reading speed of social sentences is modulated by personality traits
- 162 Federica Robertazzi, Matteo Vissani, Guido Schillaci, Egidio Falotico:** In silico brain-inspired meta-learning framework for task-specific action suppression

- 169 Claudia Bachmann, Marissa Pier Diaz, Wouter Klijn:** The Scientific Liaison Unit of EBRAINS - Our support for you!

Welcome to the 6th HBP Student Conference on Interdisciplinary Brain Research

We are excited to present the proceedings of the 6th Human Brain Project Student Conference on Interdisciplinary Brain Research, an open forum for exchange of knowledge within and across the various research fields addressed by the Human Brain Project (HBP). The conference was organized by young researchers for young researchers, as a virtual meeting for the second time now, from the 22nd to the 25th of February 2022. Reflecting the multidisciplinary nature of the HBP, the abstracts from young researchers of this year's edition cover a wide range of topics: from brain organisation, theoretical and clinical neuroscience to brain simulation and brain-inspired architectures.

LIST OF ORGANISERS

Conference programme committee

Joana Covelo | August Pi i Sunyer Biomedical Research Institute
Sandra Diaz | Forschungszentrum Jülich
Alice Geminiani | University of Pavia
Tabea Kirchner | Forschungszentrum Jülich
Carmen Lupascu | Italian National Research Council
Paschal Ochang | De Montfort University
Taylan Özden | Technical University Darmstadt
Jens Egholm Pedersen | KTH Royal Institute of Technology
Ingrid Reiten | University of Oslo
Alper Yegenoglu | Forschungszentrum Jülich

Conference organisers

HBP Education Programme | Medical University Innsbruck

Proceedings editors

Alice Geminiani | University of Pavia
Manuel Gran | Medical University Innsbruck
Judith Kathrein | Medical University Innsbruck
Tabea Kirchner | Forschungszentrum Jülich
Paschal Ochang | De Montfort University
Franziska Vogel | Medical University Innsbruck

The text of the abstracts is reproduced as submitted.

The opinions expressed in this publication are those of the authors and do not necessarily reflect the views of the Programme Committee, who accept no responsibility for the statements made or the accuracy of the data presented.

This project has received funding from the European Union's Horizon 2020 Framework Programme for Research and Innovation under the Specific Grant Agreement No. 945539 (Human Brain Project SGA3).

Preface

We are excited to present the proceedings of the 6th Human Brain Project Student Conference on Interdisciplinary Brain Research, an open forum for exchange of knowledge within and across the various research fields addressed by the Human Brain Project (HBP). Going virtual for the second time, from the 22nd to the 25th of February 2022, the 6th edition proved once more that also as a virtual meeting, the HBP Student Conference offers invaluable opportunities for extensive scientific discussions among fellow early career researchers and faculty. Through a variety of lectures, workshops, discussion sessions and social events, participants could learn about recent developments and tools in brain research, as well as interact with world-leading researchers and experts on career development, neuroethics and philosophy of the brain. At the heart of the conference were the invaluable contributions of all young researchers in the form of talks and posters, whose corresponding abstracts are presented in this book. The accepted abstracts cover a wide range of topics (brain atlases and clinical neuroscience, brain simulation and brain-inspired architectures, brain organisation and theoretical neuroscience, systems and cognitive neuroscience), introducing new and relevant problems, concepts and ideas, with the potential to inspire collaboration across research disciplines.

We would like to thank all authors for submitting their work to the 6th HBP Student Conference and all participants for making the conference a unique event for the future of brain research. We hope this selected set of abstracts can be of inspiration for new discussions, interactions and research opportunities for the whole scientific community.

Alice Geminiani, Tabea Kirchner & Paschal Ochang

INTRODUCTION/MOTIVATION

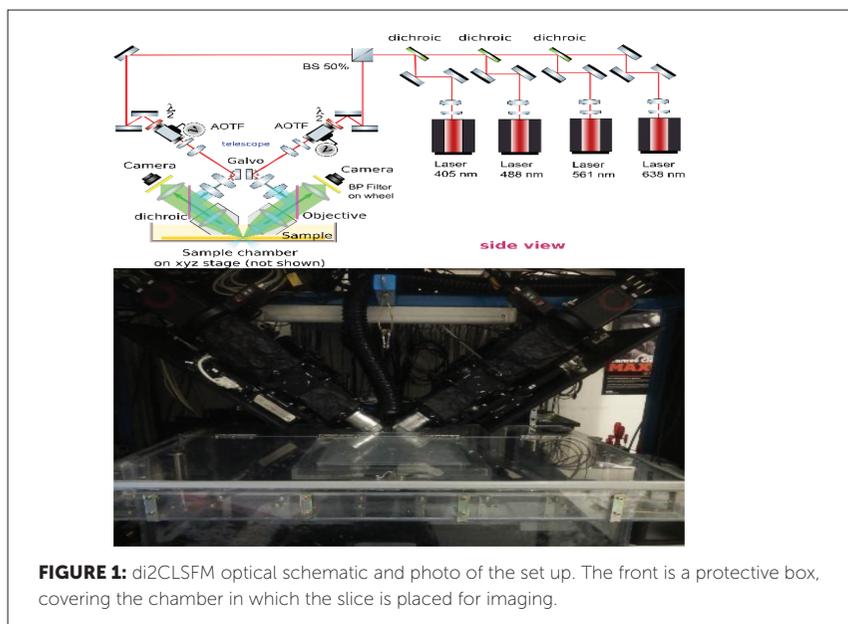

Understanding the human brain's structural and functional organization is a key aspect in neuroscience. The necessity to create a detailed map of the anatomical disposition of neurons is shared among the field and would facilitate further widespread research. Previous pipelines presented shortcomings in the form of visual artefacts, long acquisitions times and poor resolution. Here, we present a new pipeline aiming to reduce these limitations by providing high-resolution 3D reconstruction of mapped neurons of the human brain, specifically the Broca's area. The pipeline obtains this volumetric information by utilising advanced Light Sheet Fluorescence Microscopy (LSFM), optimized SHORT clearing protocol^[1] and a data management system. 49 slices from the human brain were cleared and labelled using four difference markers targeting nuclei, NeuN, Calretinin and Somatostatin which were then imaged at subcellular resolution, using a customized Light Sheet Microscope. This technique provides the grounds to acquire large-scale data volumes at optimized speeds to enable the analysis of a robust 3D reconstruction of tissue blocks up to the entire organ. In this study, we have constructed a whole human Broca's area of 4*4*2cm.

†these authors contributed equally to the work

METHODS

SHORT protocol: The aging tissue found in adult human organs are particularly difficult to render transparent due to the autofluorescence contributions. The optimized SHORT protocol is used to face this challenge, a procedure based on standard histological treatments and a refined clearing technique. Four neuronal markers were implemented in order to localize cells, highlight targets neurons and discriminate between the excitatory and inhibitory sub-populations of the Broca's area (Brodmann 44/45). The tissue ultrastructure of the SWITCH protocol^[2], a tissue processing method enabling tissue preservation and repeated labelling, combined with the clearing capability of TDE and conventional buffers were used in each of the sequentially stained 49 slices of 450 μ m thickness. With the aim of optimizing contrast during imaging, hydrogen peroxide was applied as well as alkaline antigen retrieval, followed by an optimized version of the SWITCH transformation protocol and refractive index matching with 2-2'thiodiethanol (TDE) to render the sample as transparent as possible. This enhances the depth of light penetration in addition to reducing aberrations.

Custom dual-view inverted confocal light sheet fluorescence microscope (di2CLSFM): A custom built light sheet microscope, equipped with two sCMOS cameras provide two symmetric illumination and detection pathways. As shown in Figure 1, the use of an acoustic tuneable filter and appropriate band-pass filters establish a set-up that is capable of simultaneously acquiring two channels (two laser wavelengths), halving necessary acquisition time. Each slice was acquired using 4 channels in totally (405nm, 488nm, 561nm, 638nm) as a volumetric rate of 0.5cm³/hour (47 frames per second). Two orthogonal views are leveraged, and subsequently fused computationally, to obtain almost isotropic subcellular resolution along the three optical axes.

Three-dimensional reconstruction of a human hippocampus and of Broca's area: A data management system was implemented to process the large data (≈ 14 TB/slice), combined with a machine learning technique, Convolution Neural Network (CNN) that precisely counts the neurons in 3D.

RESULTS AND DISCUSSION

Our study utilises a combination of techniques to map the neuronal architecture of the human brains. By means of specialized tissue preparation protocol, advanced light sheet fluorescence microscopy and big data analysis, we were able to analyse and to reconstruct the Broca's area of the human brain. This pipeline would not only be a useful tool in neuroscience but also for providing a tool to 3D reconstruct other tissue blocks up to the total organ for human and non-human species. This pipeline is currently being utilized to study other parts of the human brain.

All datasets acquired have been added on the DANDI platform, a platform used for publishing, sharing and processing neurophysiology data ^[3].

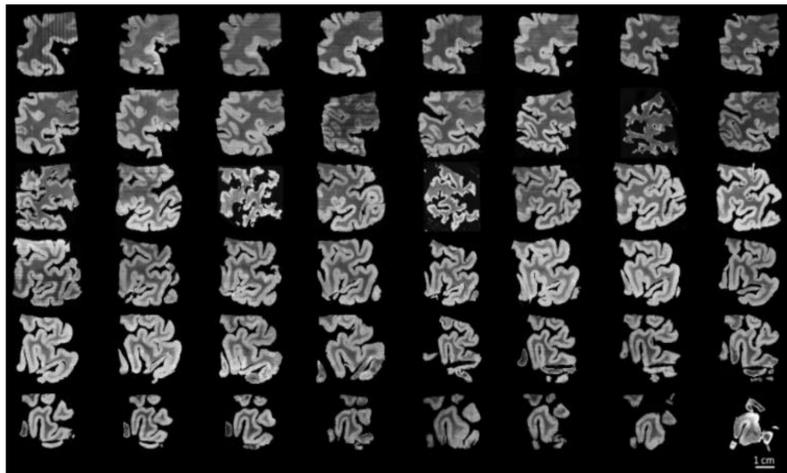

FIGURE 2: 48 slices of Broca's area imaged at a resolution of $0.56 \times 0.56 \times 0.3 \mu\text{m}^3$. The data is resliced and stitched together to obtain the final fused volume. The complete dataset has been uploaded on DANDI.

INTRODUCTION/MOTIVATION

Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by deficits in social interaction, impaired communication, and repetitive behaviours. ASD has a male bias, with a 3:1 ratio of diagnosed males and females. In this sense, it is essential to study sexual dimorphisms of ASD manifestations, and understand the pathways underlying them.

METHODS

In this work, we performed *in vivo* proton magnetic resonance spectroscopy in juvenile male and female *Tsc2*^{+/-} mice, a well-characterized ASD animal model carrying a mutation on the *Tsc2* gene, which causes tuberous sclerosis complex. Moreover, to find a link between metabolic profile and ASD core symptoms, we analysed behaviour and ultrasonic vocalizations during social and repetitive tasks. Behaviour was manually classified by a blind operator to sex and genotype, following a comprehensive mouse behaviour ethogram; Ultrasonic vocalizations were analysed regarding duration, frequency, amplitude and waveform.

RESULTS AND DISCUSSION

We found significant increase of glutamate (Glu) levels and decrease of gamma-aminobutyric acid (GABA) levels in the prefrontal cortex of transgenic females, in comparison to WT females (Glu: $p=0.0313$; GABA: $p=0.0380$). Accordingly, GABA/Glu ratio of $Tsc2^{+/-}$ females was decreased ($p=0.0152$). No significant alterations were found in males. This data reveals the existence of an excitatory/inhibitory imbalance specific to the prefrontal cortex of transgenic females. We also observed that $Tsc2^{+/-}$ females have an increased sociability ($p=0.0274$), increased repetitive behaviour ($p=0.0244$) and a less complex vocal repertoire during social task. Overall, here we uncovered an association between sex-dependent altered cortical metabolic signature and abnormal behaviour and communication in autism spectrum disorder.

INTRODUCTION/MOTIVATION

Parkinson's Disease (PD) is a progressive, neurodegenerative disorder. It affects 1% of the people over the age of 60, rising to 4% over the age of 80 [1]. The cause of the disease has not yet been clarified, with the exception of a few genes which are known to account for a small percentage of the total cases [2]. Both genetic and environmental factors are being examined as risk factors. Symptoms appear after a large number of dopaminergic neurons has died [3]. To improve the prognosis of the disease, we introduced a thorough Machine Learning (ML) approach to analyse PD data.

METHODS

1085 and 586 questionnaires from PD patients and healthy controls respectively were completed by qualified neurologists in Greek hospitals. The questionnaires contained demographic, lifestyle, pharmacological, environmental and clinical data which were stored in the Hellenic Biobank for Parkinson's Disease [4, 5] (<http://biobank-informatics.bioacademy.gr>), using MOLGENIS 8.6.3 [6]. The dataset contained 51 features for both patients and controls and 75 only for patients. Since this study focuses on the prognosis of the

disease, we wanted to include both patients and controls, so only those 51 features were used. After reformatting the data, we designed an ML approach to identify the factors that are associated with PD. Using Python programming language, we designed a system which compares various preprocessing and transforming steps, as well as ML classifiers:

- Imputers: Mean, Median, Most frequent, Knn, Iterative
- Scalers: Quantile, Max abs, Standard, Robust, Power, Min-max, Normalizer
- Encoders: One hot, Sum, Label, Leave one out, WOE, Target, M estimate, Helmert, James-Stein, Cat boost, GLMM
- Bidders: K bins discretizer
- Undersamplers: Tomek, Condensed, Random, Edited nearest, Near miss
- Feature selectors: Select percentile
- Classifiers: Nu SVC, SVC, XGBoost, Gradient boosting, Random forest, Ridge, Logistic regression, Linear SVC, Calibrated, Adaboost, Multi-layer perceptron, Linear discriminant analysis, Stochastic gradient descent, K-nearest neighbors, Decision tree, Extra tree

For each classifier, we ran numerous experiments to identify the best combination of preprocessors and transformers. For the resulting algorithms, we tuned the most important hyperparameters using the halving gridsearch algorithm, to identify the best configurations. These were later given as input to ensemble algorithms (hard voting and soft voting), to optimise the best models. Here, we ran numerous experiments to identify the best combination of optimized classifiers for the ensemble approach, and again numerous experiments to optimize the weights of the best voting soft ensemble classifier. To prevent data leakage and overfitting, the data were split into a training and a test dataset. All experiments were performed on the training set, using 10-fold cross validation. The test set was used only once, at the end of each experiment, for evaluation. Furthermore, we compared our results with those of automated ML platforms (Auto-WEKA [7], JADBio [8], RapidMiner

[9]) using the same dataset. Finally, we introduced a deep learning (DeepL) approach for analysing the data, by converting features into embeddings, a concept used in Natural Language Processing (NLP). This approach is innovative and overcomes the problem of lack of large amount of data for neural networks and lack of interpretability, since using vectors to represent each entity removes the sparse matrices' problem of inefficient computation and shows the relationship between each entity [10]. These embeddings were given as input in a Convolutional Neural Network (CNN), the architecture and the parameters of which are still being optimised, while feature maps are being constructed to better interpret features' relationships.

RESULTS AND DISCUSSION

Based on our ML approach, the ensemble classifiers have so far achieved a Matthews Correlation Coefficient (MCC) of 0.583 and an F1 score of 0.840. As this is an ongoing project, more experiments are scheduled to run, expecting to improve these 2 metrics, and to construct new informative visualisations as well. Based on our ML approach, the factors "Family History", "Age", "Gender", "Smoking-Free Years", "Coffee Status", "Total Coffee Consumption", "Daily Average Coffee", "Smoking Years" and "Religion" played, in that order, a key role in the progression of the disease. These results confirm the literature findings that PD family history, age and male gender constitute the biggest risk factors for PD, whereas smoking and coffee consumption play a protective role. Regarding the comparison between ML platforms, all three platforms require no coding skills. JADBio stood out as the user-friendliest and most automated platform. We also used it before writing our own scripts, as a preliminary data analysis tool, in order to see if our data have the potential to be classified correctly. RapidMiner was a little more complicated, but achieved good results. Auto-WEKA requires the preprocessing to be done by the user, and overfitting was also detected. However, our custom-made Python code is more versatile and we were able to implement several extra steps, analysing in depth different transformers and models. The results are summarised in table 1.

Table 1: Results comparison

Metrics	Scores				
	Machine Learning Approach	Deep Learning Approach	JADBio	RapidMiner	Auto-WEKA → configuration tested in simple WEKA
MCC	0.583	0.57	0.412	0.414 (not provided)	0.729 → 0.512
F1	0.840	0.840	0.678	0.812	0.820 → 0.779
ROC-AUC	0.8	0.8	0.789	0.788	0.859 → 0.753
Accuracy	0.8	0.8	0.729	0.742	0.878 → 0.778

The automated platforms also suggest hypertension, brain damage, and certain childhood prefectures and residence prefectures as risk factors. Although PD has already been studied using ML, this project studies, for the first time, the disease in Greece. As Greece includes numerous islands, genetic isolation can be observed to some degree, due to limited relocation. Genetic isolation also occurred due to the coexistence of two different religious communities (Orthodox and Catholic Christians) in some islands: Marriages between members of the two communities used to be rare. Thus, Greek populations should be studied to identify potential risk genes. One of the important advantages of our approach is that there is no size limit for the input data. We can also construct numerous visualisations to interpret the outcome of every step. In contrast with other approaches that often focus on accuracy, our main focus was to optimise MCC, since it takes into account the predictions for all classes equally. Finally, our extensive pipeline outperformed the 3 automated ML platforms, in terms of MCC, F1 ROC-AUC and accuracy scores. Last but not least we introduced the innovative concept of entity embeddings used to build a CNN model which outperforms every approach in terms of MCC.

INTRODUCTION/MOTIVATION

Interoception is defined as sensing, integration, and regulation of internal states of an organism by the brain. Interoceptive processing plays a significant role in the functioning of a human organism, including homeostasis and allostasis, the perception of self and other, the processing of reality, learning, and decision-making. Interoceptive processing may be enhanced or disrupted in psychiatric disorders and in anxious or stressful situations. Heartbeat-evoked responses (HERs) are evoked potentials or evoked fields (in the magnetoencephalographic (MEG) setting) that occur in response to a heartbeat event (Baranauskas et al., 2017). Trait anxiety is viewed as a fairly stable characteristic in connection to personality. Experiencing state anxiety more frequently and perceiving the world as being generally unsafe and threatening are the major features of trait anxiety (Wiedemann, 2001). The amplitude of heartbeat-evoked responses time-locked to the processing of external stimuli has been shown to disrupt exteroceptive processing (Park et al., 2014). In our recent work we showed that state anxiety disrupts learning and decision making in a volatile environment, decreasing the amount to which individuals update their beliefs using feedback (Hein et al., 2021). Analysing the HER locked to the T-wave of the cardiac cycle, we aim to assess the degree to which the HER amplitude modulates trial-by-trial belief updating and learning, as a function of trait anxiety. Investigating how interoception can modulate learning in high trait anxiety, we can discover important characteristics of anxiety as a personality trait as well as a clinical condition. This knowledge can improve our understanding of mental health conditions as many of them include anxiety as a symptom, which can later used in the development of better treatments for such conditions.

METHODS

For recording brain activity, we are using magnetoencephalography (MEG) – the 306-channel magnetoencephalographic machine 'Neuromag Vector View' (Elekta Oy, Finland), located in the Moscow MEG Centre (Moscow, Russia). Along with MEG, we record ECG and electrooculogram (EOG) using the bipolar channels integrated in the system. Magnetoencephalography is characterized with the good temporal resolution similar to electroencephalography (EEG), which makes it a useful tool to investigate such things as neural evoked responses, and at the same time its spatial resolution is stronger than EEG, so it can be used for localizing the source of the signal with better precision. Our experimental task (Fig. 1) consists of three blocks: resting state, reward learning task block 1, and reward learning task block 2 Binary choice decision-making task with contingencies that change over the course of learning. Participants need to complete two blocks, each of which consists of 160 trials, and their goal is to determine which one of the two visual icons (always either a blue or an orange circle) leads to a reward (5 points). We are using the STAI-T scale (Spielberger, 1983) to measure participants' trait anxiety levels.

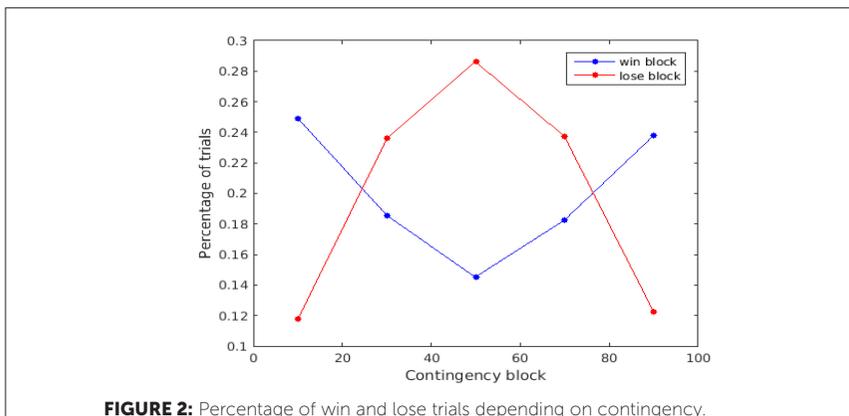

RESULTS AND DISCUSSION

We acquired MEG, ECG, and behavioral data from 41 participant: 20 participants with high trait anxiety (STAI score: > 45) and 21 participants with low trait anxiety (STAI score: < 35). Analysis of the behavioral data revealed significant differences between the low trait anxiety and the high trait anxiety groups in model-free and model-based variables. On the one hand, the average winning rate – the percentage of winning trials – for the low trait anxiety group equals to 0.65 (SEM 0.01), while the average winning rate for the high trait anxiety group is 0.63 (SEM 0.03). These values are significantly different using permutation tests, and the p-value is 0.0186. On the other hand, preliminary analysis of the data using the Bayesian computational model that was the best model explaining the data in a previous study of the group (Hein et al., 2021) demonstrates that high trait relative to low trait anxiety leads to reduced learning through an attenuation of prediction errors updating beliefs. We have yet to complete our analysis of the HERs, however, by far, we have made an interesting

OBSERVATION

The HER amplitude is higher in both groups in lose trials than in win trials. Since we are analyzing the HER amplitude which is time-locked to the T-wave that is preceding the feedback, by the time we can observe the HER (around 150 ms after the T-wave), the feedback does not yet appear. So, the HER amplitude appears to be reacting to the outcome of the trial before the outcome is known to the participant. We also observed that most lose

trials happened during the 50/50 contingency blocks (Fig. 2), so possible explanations include some kind of processing of 'loss anticipation' occurring in participants.

The plans for further analysis in our project include the following steps:

- The behavior of both groups in the learning task to be characterized using a hierarchical Bayesian model of decision-making to link trial-to-trial HER measures to dynamic learning.
- Our aim is to focus on the trial-by-trial modulations of the HER preceding the outcome and see how the amplitude modulates with learning in the trial from the feedback information (combining analysis of the MEG HER and the trajectories of learning in a Bayesian computational model).

INTRODUCTION/MOTIVATION

Premenstrual dysphoric disorder (PMDD) is a depressive disorder [1] characterized by severe negative mood and physical symptoms that occur after ovulation (luteal phase) and disappear with the onset of menstruation (i.e., during the follicular phase). There is evidence that imbalance of excitatory (E) and inhibitory (I) neurotransmission caused by abnormal sensitivity of GABAergic receptors to progesterone metabolite allopregnanolone plays an important role in PMDD [2]. We hypothesised that E/I imbalance in PMDD will be evident in the cortical regions rich in GABAergic neurons, such as the primary visual cortex (V1), i.e., even beyond brain areas involved in mood control. To test this hypothesis, we used electrophysiological and psychophysical measures of inhibition efficacy in the visual cortex – visual perceptual suppression ('*spatial suppression*'; [3]) and visual *gamma response suppression index* (GRSI; [4]).

METHODS

We recruited 20 women suffering from PMDD according to the C-PASS questionnaire ([5]) and 27 age-matched control women (Age: 18-40, 28.4±5.6), who had no/mild premenstrual symptoms according to a retrospective questionnaire. The criteria for inclusion were regular menstrual cycle and absence of hormonal (e.g. contraceptive pills) or antipsychotic treatment. The participants were investigated twice: during follicular (asymptomatic) and luteal (symptomatic) phases of the menstrual cycle; the phase of the visit was balanced between visits and participants. The presence of the particular phase

(luteal/follicular) was confirmed by biochemical analysis of progesterone and estradiol concentration. During both visits, the women underwent magnetoencephalography (MEG) and psychophysical testing. MEG was recorded while the participants looked at large (18°) high-contrast circular gratings, either static or moving at one of three velocities: 'slow': 1.2°/s, 'medium': 3.6°/s, 'fast': 6.0°/s. Stimuli of this type cause reliable increase in gamma (40-90 Hz) power in the V1 – 'gamma response' (GR). The GR is generated through interaction of parvalbumin-containing inhibitory neurons and principle cells [6]. Frequency of the GR is known to increase linearly with increasing visual motion velocity, while its power demonstrates nonlinear changes: it normally increases up to 1.2-3.6°/s ('suppression transition point') and then decreases with further increase of motion velocity [4,7]. The GR attenuation at fast velocities can be explained by stronger inhibitory regulation (and lower E/I ratio) associated with strong excitatory drive [4]. To approximate the 'suppression transition point', we estimated GRSI as:

$$\left(\text{Power}_{\text{STATIC}} * 0 + \text{Power}_{\text{SLOW}} * 1.2 + \text{Power}_{\text{MEDIUM}} * 3.6 + \text{Power}_{\text{FAST}} * 6.0 \right) / \left(\text{Power}_{\text{STATIC}} + \text{Power}_{\text{SLOW}} + \text{Power}_{\text{MEDIUM}} + \text{Power}_{\text{FAST}} \right).$$

During a separate psychophysical experiment, participants detected the direction of motion of small (1°) and large (12°) high-contrast vertical gratings. The gratings moved at a constant velocity, but the duration of their presentation gradually decreased. We estimated the minimal time required to discriminate the motion direction of small ($\text{Threshold}_{\text{SMALL}}$) and large ($\text{Threshold}_{\text{LARGE}}$) grating. It has been shown previously that it usually takes people longer to discriminate motion direction of a large grating than of a small grating because of the suppression of neuronal responses caused by the activation of the inhibitory surround by large high-contrast stimuli (i.e., 'surround suppression'). Thus, the longer time required to discriminate the direction of the large grating indicates stronger inhibition in the visual cortex [8].

RESULTS AND DISCUSSION

All participants from the PMDD group reported severe premenstrual symptoms during at least two menstrual cycles. Similarly to the results of the previous study that included women with severe PMDD [9], our participants had reduced level of progesterone in the luteal phase (Mann-Whitney test, $U=168.5$, $p=0.015$) as well as an elevated estradiol/progesterone ratio in the luteal phase (Mann-Whitney test, $U=168.5$, $p=0.005$).

In both PMDD and control participants the GR frequency increased from follicular to the luteal phase ($F(1,42)=7.3$, $p=0.01$). No group differences in the GR frequency or Group x Phase interaction was found. Unlike GR frequency, GR power did not depend on the phase of the cycle, but demonstrated significant Velocity x Group interaction ($F(3,129)=3.2$, $p=0.025$): women with PMDD were characterized by stronger GR during the 'medium' and 'fast' motion conditions, but not the 'static' one, thus indicating a shift of the 'suppression transition point' to higher motion velocities. Indeed, the GRSI was significantly higher in women with PMDD than in control subjects ($F(1,42)=5.1$, $p=0.029$). Moreover, in the PMDD group the GRSI was significantly higher during luteal compared to follicular phase of the menstrual cycle ($F(1,17)=5.3$, $p=0.035$). Generally higher GRSI in PMDD than in control group suggests impaired E/I balance regulation in PMDD patients. The increase of the GRSI in women with PMDD during luteal as compared to follicular phase of the cycle suggests that E/I balance in their visual cortex is especially strongly compromised during the symptomatic phase. Despite the observed alterations, the GRSI in women with PMDD did not correlate with the symptoms severity ($\text{GRSI}_{\text{LUTEAL}}$: Spearman $R=0.014$, $p=0.95$). It is likely, that while impairment of E/I balance regulation in PMDD is widespread, the mood symptoms of PMDD are associated with E/I imbalance in specific, mood-related brain areas.

In the psychophysical experiment the reliable data were obtained from 23 controls and 13 PMDD participants. While $\text{Threshold}_{\text{SMALL}}$ did not differ between groups and phases, $\text{Threshold}_{\text{LARGE}}$ in PMDD significantly decreased during the luteal as compared to follicular phase ($F(1,11)=5.6$, $p=0.038$), suggesting reduction of neural inhibition during the symptomatic phase. For $\text{Threshold}_{\text{LARGE}}$, there was also Group x Phase interaction ($F(1,32)=5.2$, $p=0.03$): during follicular (but not luteal) phase the $\text{Threshold}_{\text{LARGE}}$ tended to be higher in the PMDD than in the control subjects ($F(1,32)=3.7$, $p=0.063$). Interestingly, the $\text{Threshold}_{\text{LARGE}}$ measured during the luteal phase correlated positively with severity of their premenstrual symptoms (Spearman $R=0.58$; $p=0.023$). These findings suggest the presence of a compensatory, possibly 'top-down' regulatory mechanism in PMDD patients that enhances neural inhibition in V1, putatively through activation of somatostatin-containing inhibitory neurons [10].

In conclusion, the results of both MEG and psychophysical studies indicate a decrease in neural inhibition in the visual cortex in women with PMDD during the luteal – symptomatic – phase of the menstrual cycle. Our results

also suggest that the regulation of E/I balance in the visual cortex in women with PMDD is atypical in both luteal and follicular phases. Although changes in E/I balance in the visual cortex are not directly related to the psychoaffective symptoms of PMDD, they may shed light on the neural mechanisms of this disorder.

INTRODUCTION/MOTIVATION

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and presence of repetitive behaviors. Recent evidences suggested that microbiome may play a role in the etiology of ASD. However, the mechanisms of these effects are still poorly understood. Some evidences suggest that the gut can affect brain function through metabolite secretion, host immune response, altering the activity of the stress-associated hypothalamic–pituitary–adrenal axis and regulating the biosynthesis of active neuropeptides. Neuropeptide Y (NPY) is one of the most potent orexigenic neuropeptides found in the central and peripheral nervous systems with roles in multiple physiological processes including neuronal excitability, learning and memory and regulation of intestinal microbiota. But, it remains unclear whether behavioral disorders associated with dysbiosis of the intestinal microbiota, including ASD, are also under the control of the NPY system. The proposed work will evaluate gut microbiome relative levels and brain NPY system expression in neurofibromatosis type 1 (NF1) mice, a well-characterized ASD animal model.

METHODS

Here, juvenile female and male NF1 mice were used. Brains were removed and brain regions, namely hippocampus and amygdala, were dissected.

Additionally, we collected stool samples directly from the colon. All samples were stored in RNA later at -80°C until further use. mRNA from brain and colon samples were extracted using RNeasy Lipid Tissue and RNeasy PowerMicrobiome[®] Kit (Qiagen, Hilden Germany), respectively, according to the manufacturer's instructions. Real Time PCR (RT-PCR) on microbial samples was performed using primers for the genera *Lactobacillus*. 16S were used as a bacterial endogenous control for qRT-PCR experiment. For gene expression analysis from brain samples, primers for *npv*, *y1r*, *y2r*, *y5r* were used. *B2m* and *ywhaz* were used as housekeeping genes to normalize NPY mRNA changes. Importantly, all experiments used littermates as controls. Statistical analysis was performed using the Mann-Whitney test in GraphPad Prism 6.0 (GraphPad software, Inc., San Diego, CA, USA).

RESULTS AND DISCUSSION

The present study reported dysregulation of *Lactobacillus* population in the gut of NF1 mice, with a decrease in *L.Reuteri* and an increase in *L.Rumni*. In addition, we also reported changes in NPY and NPY receptors expression in amygdala and hippocampus brain regions of NF1 animal in a sex-dependent way. Indeed, NF1 males showed an increase in NPY in hippocampus and a decrease in Y_2R expression in amygdala comparing with their WT littermates. On the other hand, no changes were detected in transgenic females. This study identified bacterial species that are sensitive to an autism-related mutation as well sex-dependent changes in brain NPY, pointing to the importance of considering the gut-brain axis in treatment of this disorder.

INTRODUCTION/MOTIVATION

Mental health today is a burden on a global level with various psychiatric disorders leading to a lower quality of life, a significant number of deaths and a higher pressure on healthcare systems. It is known that mental disorders influenced around 1 billion people worldwide in 2019 (point prevalence: 970,070,243) [1]. As developing more effective treatments for the most common mental disorders is of high priority for international public health, substantial research is nowadays dedicated to this issue. This includes studies where emphasis is put on biological and mechanistic understanding of the brain. For example, the PsychENCODE [2] initiative provides various molecular and genetic data generated from brain tissue and already presents some insights into the molecular mechanisms of gene regulation for psychiatric disorders such as autism spectrum disorder, bipolar disorder, and schizophrenia. These data are often referred to as multi-omics and include but are not limited to gene or protein expression read-outs, mutations, DNA methylation. In order to achieve a higher level of interpretability, we aim to develop a method based on a graph neural network which leverages prior knowledge of gene-gene associations in the form of protein-protein interaction network and multi-omics data generated from brain tissue. Methods for integration of different molecular data types such as graph neural networks for disease gene predictions have already been successfully applied in the context of cancer [3] and might be suitable to integrate heterogeneous data from the brain.

METHODS

We apply graph attention network model [4] to integrate gene expression data with protein-protein interaction data to identify candidate genes related to schizophrenia. Protein-protein interactions were retrieved from STRING database [5] and are used as a graph structure for the graph attention network model where each node corresponds to a gene. Gene expression data was extracted from PsychENCODE resource [6] in a form of a matrix where each entry represents the expression level of a particular gene in a given sample. This gene expression was pre-processed such that the final matrix contains samples that represent either control group or patients diagnosed with schizophrenia and genes that are protein-coding and have non-constant expression (the gene should have standard deviation of gene expression values across all samples higher than a certain threshold). The final gene expression matrix was used as a feature matrix for the model with each row was taken as a feature vector for respective node in the graph. After model training, we obtain prediction scores for each node/gene to identify candidate biomarker genes for schizophrenia.

Along with gene prediction task, we assess the value of including both tissue-agnostic and brain-specific protein-protein interaction as an additional data source and the advantages of graph neural networks as opposed to other deep learning architectures that have been used on this data so far. Brain-specific protein-protein interaction data was retrieved from the following databases: IID (Integrated Interactions Database), GIANT (Genome-wide Analysis of gene Networks in Tissues), and GTEx (Genotype-Tissue Expression). We run the model for each protein-protein interaction network individually and for each case we evaluate model performance.

RESULTS AND DISCUSSION

We compared the performance of the model with other methods for disease gene prediction such as EMOGI [3] and DeepWalk [6] as well as classifiers which do not consider network topology such as random forest and support vector machine. Based on different metrics we calculated, the model on average outperforms other machine learning architectures that can be used on this data. However, according to all model performance metrics, we do not have an advantage from having brain-specific protein-protein interactions over tissue-agnostic protein-protein interactions when using these networks as a prior knowledge of gene-gene associations.

The result of prediction task is a list of genes that are candidate biomarker genes for schizophrenia which we put into a context using gene set enrichment analysis. Moreover, we achieve a higher level of interpretability by directly utilizing the attention weights which are additionally learned during model training. Those attention weights mean the importance of expression values of one gene for disease state prediction made for another node. They provide us with new insights on gene relations and allow us to visualize the new graphs that our model has learned. Therefore, by exploiting attentional weights, we benefit in terms of model explainability and overcome the problem of low reliability of protein-protein interaction networks.

Further, we will extend the method to allow the inclusion of other molecular data types such as ChIP-Seq (chromatin immunoprecipitation sequencing), DNA methylation, and genotype data in an integrative manner. The approach should not only allow for integration of multiple data types into the model, but we will implement an interpretation framework for model explanation. Then, the framework will be used to identify and contextualize biomarker

genes for other psychiatric disorders such as bipolar disorder and autism spectrum disorder.

INTRODUCTION/MOTIVATION

Tuberous Sclerosis Complex (TSC) is a rare genetic disorder characterized by severe epilepsy, cerebral hamartomas and intellectual disability [1]. Epilepsy is the most common neurological complication in TSC and up to 80–90% of individuals with TSC develop epilepsy at some point in their lifetime [2,3]. Further studies are needed to understand and better characterize the mechanisms behind this comorbidity in TSC. Similarly to the human condition, Tsc2^{+/-} mice display hyperactivation of the mammalian target of rapamycin (mTOR) pathway, which theoretically causes a propensity to exhibit increased epileptic activity [5,6]; however, there is little evidence in the literature supporting this assumption. We aim to determine whether Tsc2^{+/-} mice have altered susceptibility to seizures and explore how sex, age and time of day influence Tsc2-related seizure severity and locomotor activity.

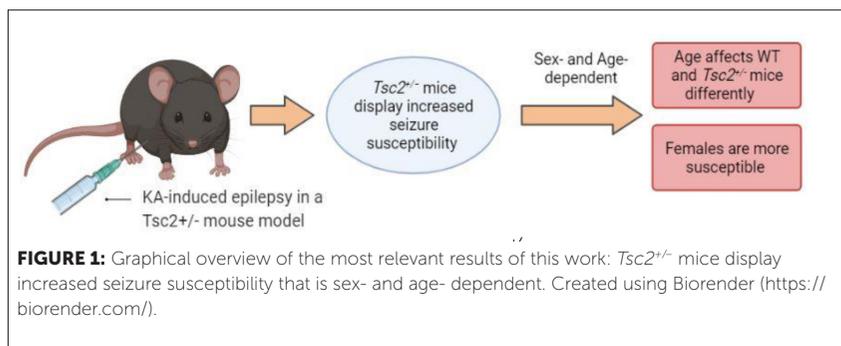

METHODS

We assessed seizure susceptibility and progression in a Tsc2^{+/-} mouse model using the chemical convulsant kainic acid (KA), a potent agonist of the AMPA/kainate class of glutamate receptors [7]. Both male and female animals at late adolescent and adult age were evaluated during non-active and active periods (zeitgeber time (ZT) 6 and 18, respectively).

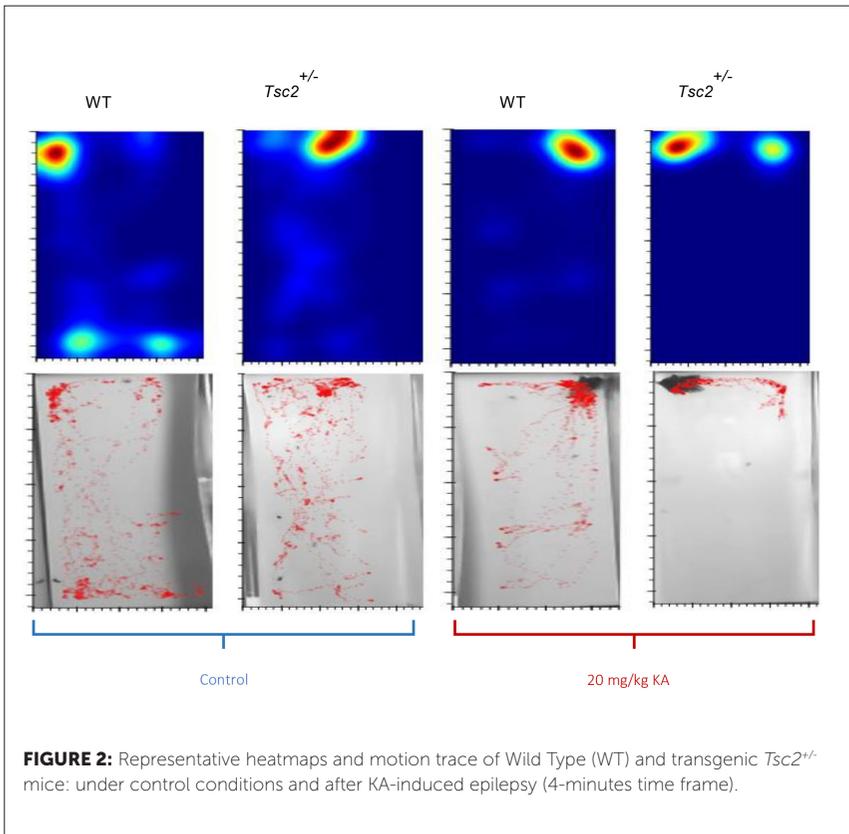

The animals were recorded for 20 minutes under control conditions (saline, i.p.) and for 100 minutes after KA administration (20mg/kg, i.p.). Seizure severity was determined by integrating individual scores per mouse during a 4-minute timeframe 15 minutes after KA administration according to a modified Racine scale as previously described by *E. AKYUZ et. al* [8]. Locomotor behaviour was monitored during the same timeframe using related metrics extracted from top-video recordings using *ezTrack*, an open-source video analysis pipeline for the investigation of animal behaviour [9]. The metrics under study included: distance travelled over time (cm), percentage of time in which the animals were not moving (%) and the percentage of animals exhibiting exploratory behaviour (%) - characterized by the movement of the animal to the centre of the field.

RESULTS AND DISCUSSION

Tsc2^{+/-} mice displayed an increased susceptibility in both ages and at both time periods (Ordinary One-Way ANOVA test, $p < 0.0001$). Moreover, transgenic and Wild Type (WT) mice were differently affected by age: *Tsc2*^{+/-} mice exhibited a constant and severe susceptibility not dependent on age (Kruskal-Wallis test, $p = 0.8$); while WT mice exhibited an increased susceptibility at earlier stages of development that significantly decreased on adult age (Kruskal-Wallis test, $p < 0.0001$). Furthermore, susceptibility to seizures was sex-dependent, with females being more susceptible in both ages (Kruskal-Wallis test, $p < 0.001$) (**Figure 1**). Regardless of mice activity levels, analysis on the respective motion tracks revealed that WT mice showed increased exploratory behaviour (44.44% WT showed exploratory behaviour at ZT6 and

ZT18) while $Tsc2^{+/-}$ mostly preferred to remain in the same location or move closer to the walls of the field (18.75% $Tsc2^{+/-}$ showed exploratory behaviour at ZT6 and 22.22% at ZT18) (**Figure 2**). All animals exhibited overall reduced movement during the night-time period (Kruskal-Wallis test, $P < 0.05$). With this work we demonstrated for the first time that $Tsc2^{+/-}$ mice display an increased susceptibility following KA administration, supporting the use of this model in future TSC-related epilepsy research. Furthermore, we showed that KA-induced epilepsy is sex- and age- dependent and that mice activity is affected by daytime period.

INTRODUCTION/MOTIVATION

The alternation of wakefulness and sleep supports the brain energetic and cognitive efficiency in a large variety of high-level functions: among them, the capability of fast incremental learning from a few noisy examples, as well as the ability to associate similar memories in autonomously-created categories, to combine contextual hints with sensory perceptions and to maintain the metabolic cost of brain functions within a budget notwithstanding the progressive increment in knowledge and performance. Sleep is known to be essential for a performance, but the mechanisms underlying its role in supporting learning and energetic management are still to be clarified. This work leverages the recent experimentally driven hypotheses of apical isolation and apical drive [1][2] principles to induce in a model some of the favourable energetic and cognitive effects associated to NREM and REM sleep, reconciling the experimental observation of [11][12]. Also, we follow the apical amplification [3] concept to combine context and perception during training during awake learning. This way, we added REM to the brain states accessible to the thalamo-cortical spiking model [4][5] that demonstrated the effects of incremental awake-NREM learning cycles. Specifically, we investigate both the effects of sleep on the internal synaptic structure of the network and

on its neural activity in a two-area model. We demonstrate complementary homeostatic and associative effects of slow-wave and dreaming-like phases of sleep on cortico-cortical synapses and we show the consequent beneficial energetic consumption effects while keeping the sleep-induced cognitive effects.

METHODS

In this work, we improved to REM simulation the data-driven thalamo-cortical spiking model [4][5] that was already able to carry out cognitive tasks (such as object recognition or decision-making), while expressing realistic brain dynamics in different states (AWAKE and NREM) through the modulation of adaptation, synaptic asymmetry and inhibitory conductance parameters. Specifically, we implemented a multi-area thalamo-cortical spiking model in NEST[6] made of adaptive exponential conductance based excitatory and inhibitory neurons: the thalamic layer projects into the cortical layer through symmetric top-down synaptic connections. The cortical layer, in turn, is organized into two areas recurrently and reciprocally connected, as depicted in Figure 1A. During the awake phase, a visual input [7] is encoded into the thalamic layer and projected to the cortical one: each area in the cortex has access to a different portion of the visual input with a region of overlapping. Plastic synapses are updated in the training and sleeping phase through a STDP (Spike-timing-dependent plasticity) synaptic rule. The training of the network is implemented with a combination of lateral contextual and perceptual signals to correctly sculpt the synaptic weight encoding for the learnt examples, analogously as in [4], in accordance with an Apical Amplification situation [3]. The training protocol is unsupervised, meaning that no information concerning the perception class is provided to the cortex. During the classification phase, on the other hand, the network is provided with a perceptual signal only. In the sleeping phase, the network is not exposed to any perceptual signal and is stimulated by a random lateral signal. During REM sleep the network adaptation is decreased with respect to the awake state [10] while all cortico-cortical connections are active and plastic, in particular those connecting the two areas, implementing an Apical Drive-like situation [1,2]. To emulate the NREM sleep, on the other hand, the adaptation is increased [10] and inter-area cortico-cortical connections are cut, in accordance with the Apical Isolation principle [1,2].

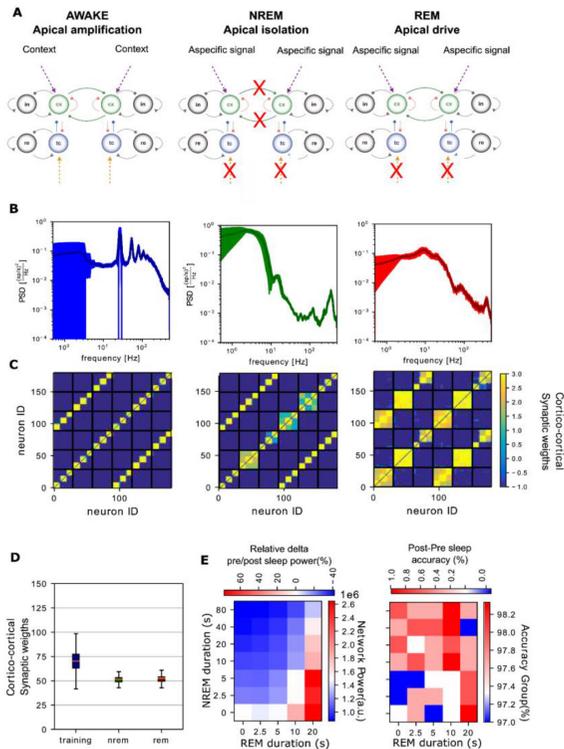

FIGURE 1: Awake-NREM-REM cycle effects. **A)** Network structure: two-area thalamo-cortical model with interconnected cortical populations in awake, nrem and rem phases (Apical Amplification [3], Apical Isolation and Apical Drive principles [1,2]) **B)** Network's Power Spectral Density (PSD) in awake (left), NREM (center), REM (right) stages. Results are comparable with what experimentally observed[9]. **C)** Associative effects of sleep on the cortico-cortical synaptic structure of a network trained over 3 examples per 3 categories. Awake (Left): each subgroup of cortical neurons is orthogonal to the others; NREM stages (center) intra-area connections between groups of neurons responding to similar perceptions are strengthened, while stronger synapses are subjected to homeostatic depression (accordingly with the "shy hypothesis" [12] and selective reinforcement [11]); REM (right) inter-area connections between groups trained over similar perceptual stimuli are strengthened. **D)** Homeostatic effects of sleep: box-plots describing the cortico-cortical synaptic weights distribution after the training (blue), NREM (green) and REM (red) phases. **E)** Effects and Calibration of NREM and REM cycles duration. (Left) Network power consumption during a classification task and relative difference ($\Delta_{\text{post-pre}}$) compared to the pre-sleeping phase. (Right) Post-sleep classification accuracy, and relative improvement compared to pre-sleep, versus NREM and REM duration after a training over 3 examples per 3 categories.

RESULTS AND DISCUSSION

We show the beneficial effects of sleep on both classification performances and energy consumption; to show the beneficial effects of sleep on the network cognitive tasks, we tested the classification performances when classifying the MNIST [7] dataset after a balanced training over 3 examples belonging to 10 classes. First, we calibrated the NREM and REM stages duration, as shown in Figure 1D: the optimal combination is at 40s of NREM and 10s of REM duration, corresponding to a reduction of 22% in the network power consumption and an improvement of 1% in classification accuracy (in agreement with experimental data [8,11]). The power spectra of the network activity in awake classification, NREM and REM stages (shown in Figure 1B) are comparable with what is expected by experimental biological recordings [9]. In Figure 1C and D, we respectively show the associative and homeostatic effect of sleep on cortical synapses. Indeed, as depicted in Figure 1C, cortical groups trained over different examples belonging to the same class (i.e. described by similar perceptual signals) are grouped together in each area during the NREM phase whereas groups of neurons belonging to different cortical areas are associated during the REM phase. This association is implemented by cortico-thalamo-cortical activation loops mediated by inhibitory neurons causing different groups of cortical neurons to respond to similar perceptual stimuli with a contemporaneous up-state in the sleeping phase. Figure 1D, on the other hand, demonstrates the homeostatic effect of sleep on cortico-cortical synapses leading to a general reduction of synaptic weight distributions during the sleeping phase.

ACKNOWLEDGEMENTS

This work has been supported by the European Union Horizon 2020 Research and Innovation program under the FET Flagship Human Brain Project (grant agreement SGA3 n. 945539) and by the INFN APE Parallel/Distributed Computing laboratory. INTRODUCTION

Simulation of the brain activity is a stimulating challenge that is addressed at different scales. Models of brain function are currently being developed, including both at micro and macroscale, to increase regional fidelity and to lead to more accurate whole-brain dynamics. Mean Field(MF) is a widespread formalism that provides a computational advantageous representation of the neuronal population dynamics, oversimplifying the physiological properties of an entire neuronal circuit through ad-hoc transfer functions(Boustani and Destexhe,2009; Zerlaut et al.,2016, 2018). The MF models developed so far are tailored to the cerebral cortex but may not be effective to capture other brain regional dynamics, e.g. the cerebellar cortex, due to their specific structural organization. Here, we aim to develop an advanced MF model of the cerebellar circuit considering its complex neuronal features, multi-layer organization, local connectivity deriving from the quasi-crystalline geometry(D'Angelo et al.,2016). Specifically, we present a MF model of the granular layer(GRL MF), the cerebellar input stage, retaining the salient properties of its neuronal populations, Golgi cells(GoC) and Granule cells(GrC). Our model will be used to provide theoretical insight on the cerebellar input stage and represents the promising first brick for the development of a whole-cerebellar advanced MF model.

METHODS

The design of the GRL MF model started from an accurate and extensive knowledge of the GrC and GoC structural and functional properties within the cerebellar microcircuit. Population-specific Transfer Functions(TF) allow translating spiking patterns into time-continuous global outputs. A semi-analytical TF fitting was inspired to that already validated for the implementation of MF models of isocortical circuits made of excitatory and inhibitory neurons (Carlu et al.,2020). We expanded this framework introducing topological parameters that modelled the biological properties of GrCs and GoCs so enabling a physiological interpretation of the network output. The granular layer detailed reconstruction(placement and connectivity), generated by a scaffold model approach, was used to set realistic probability for each connection type(K). Quantal synaptic conductance and synaptic time decays(Q, τ) are set relying on detailed synaptic model (Casali et al.,2019; De Schepper et al.,2021) The reference functional target was the neuronal spiking activity that emerged in network simulations(in-vivo conditions) using E-GLIF single-point neurons optimized for each population (Geminiani et al., 2018, 2019). The population frequencies were extracted from simulation results using the Brain Scaffold Builder framework (De Schepper et al.,2021) interfacing with the NEST simulator.

TF equations were adapted to model the alpha synapses consistently with the E-GLIF models in the network.

The GoC TF was computed maintaining the excitatory contribution from mossy fibres and GrC separately, enabling it to investigate the specific contribution of the two excitatory synapses to the granular layer dynamics. Furthermore, for each population we defined the eligible frequency ranges combinations of its presynaptic populations, to fit the TF on the plausible granular layer working frequencies. The GRL MF model equations were written with population inter-dependent transfer functions, and the model prediction was tested for different driving inputs coming from mossy fibres(v_{drive}). The MF time constant(T) was fixed to 20ms(Di Volo et al.,2019).

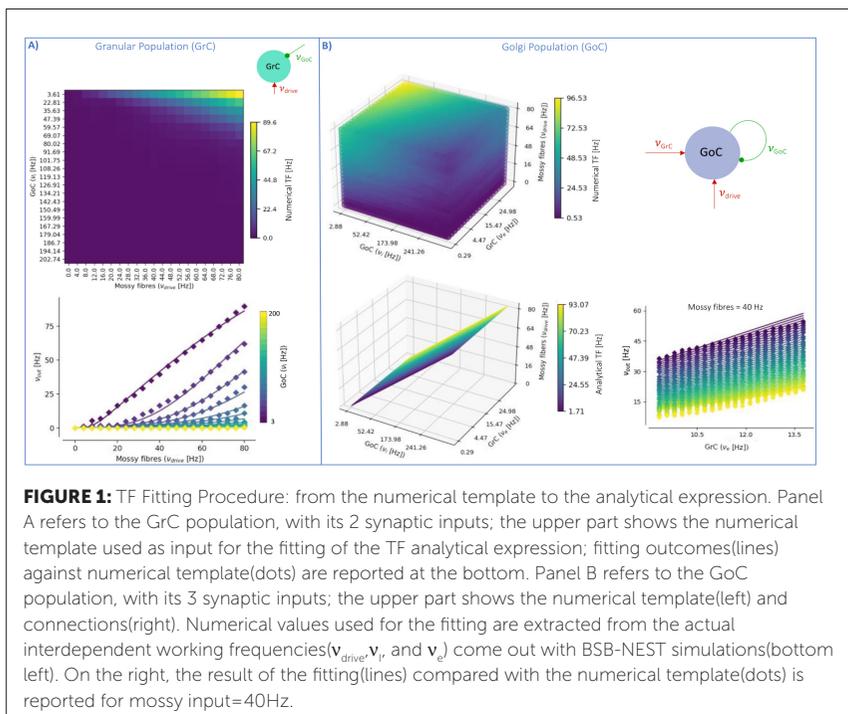

RESULTS AND DISCUSSION

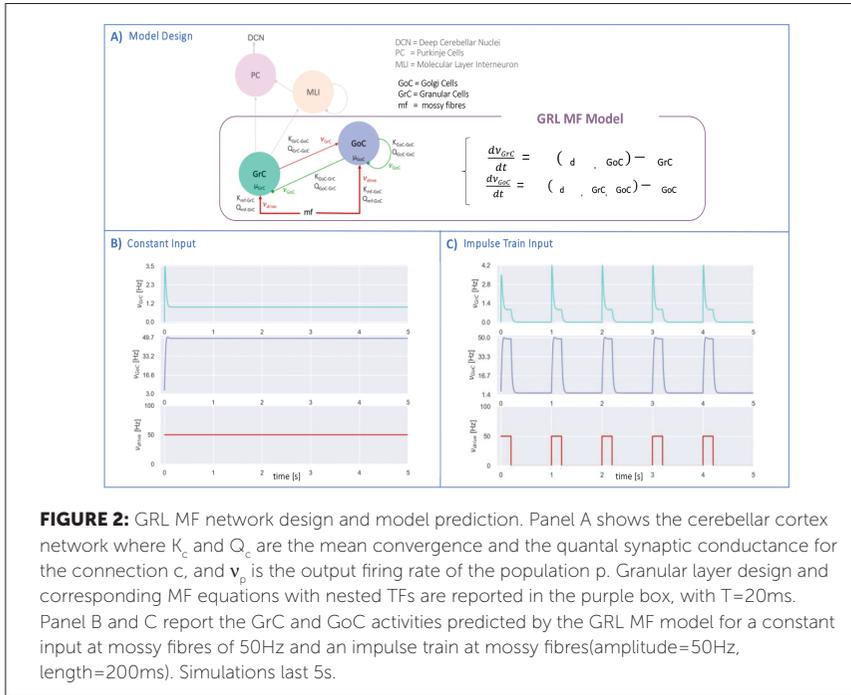

The MF formalism proposed here for the first time is a bottom-up approach tailored on the biological properties of the granular layer of the

cerebellar cortex. We exploit all the advantages of the MF versatile formalism, which provides an established pipeline to reduce spiking networks activity to realistic average models of neuronal population dynamics.

In the fitting procedures to define the GrC and GoC TFs, we included fine-tuned parameters to maintain a strong physiological reference. The numerical templates(2D for GrC population and 3D for GoC population) and the output of the fitting(analytical TFs) are reported in Figure 1.

First order GRL MF model equations are reported in Figure 2–Panel A, with the granular layer network included in the context of the cerebellar cortex. GrC and GoC dynamics were simulated with the GRL MF based on the nested TFs. We reported the output for two different input patterns (Panel B and C), which correspond to in-vivo recordings of the Granular Layer response to different sensorial stimuli (Svensson et al.,1997).

Currently, we are comparing the GRL MF output with the Local Field Potential (LFP) recorded with extracellular electrophysiological experiments (HD-MEA) to validate the population activities generated by the GRL MF with biological recordings on the same spatial scale. Once the GRL MF validation is completed, we will move up to the Molecular Layer to extend our formalism to all the cerebellar neuronal populations. Then we will expand our formalism to the second order to include covariance terms. Finally, this cerebellar-specific MF will be integrated in a whole-brain framework, The Virtual Brain (TVB), to investigate the impact of complex cerebellar responses into whole-brain dynamics. Indeed, the cerebellar impact on whole-brain activity simulated with TVB has been preliminarily demonstrated (Sanz-Leon et al., 2013; Palesi et al., 2020) by including specific cerebellar nodes.

ACKNOWLEDGEMENTS

INTRODUCTION / MOTIVATION

The study of the human brain is probably one of the greatest challenges in the field of neuroscience due to the inner complexity of the human nervous system. While ongoing developments in experimental neuroscience are increasing the availability of novel recordings and reconstructions, innovative modelling methods and flexible simulation environments are being developed to capture their complex behaviour. Moreover, studying smaller and simpler organisms, such as the nematode *Caenorhabditis Elegans* (*C. elegans*), is useful in bringing insight into the dynamics of more complex neuronal structures. *C. elegans* is a nematode (roundworm) of about 1 mm in length with a small nervous system consisting of less than 1000 cells across all sexes and around 15000 connections [1, 2]. Due to its relative simplicity, the nervous system of *C. elegans* is almost completely described, generating detailed connectomes of geometrically distributed neurons and synapses. These detailed descriptions may lead to complicated models, implying more computationally demanding, potentially intractable simulations of the dynamic behaviour. This increased complexity is a side effect of the detailed modelling of the internal structure whereas often one is only interested in the peripheral input-output behaviour.

METHODS

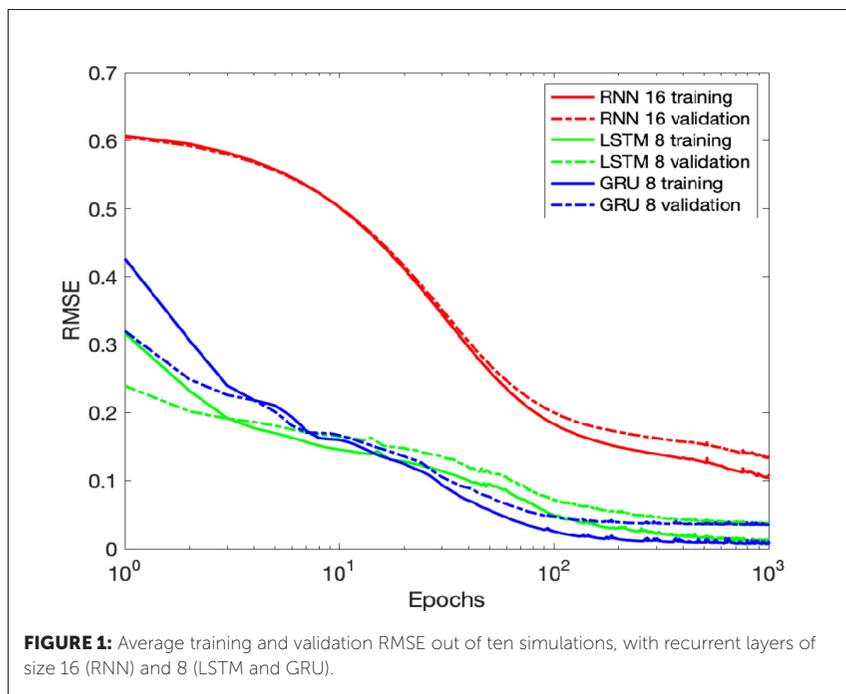

We propose a methodology for generating completely data-driven black-box models of the neuronal behaviour of organisms using only peripheral information of the system. We start from synthetic data, extracted from a high-fidelity model of *C. elegans*, which comprises the complete connectome

of the adult hermaphrodite, with 302 multi-compartmental neurons and 6702 synapses. We simulate two behavioural scenarios in the NEURON simulator [3], the Forward Crawling Motion (FCM) and the Nictation (NIC), with scenario-specific neurons stimulated according to the behaviour being replicated. In the FCM scenario four specific neurons are stimulated and the output is observed in sixteen neurons known to show a strong response in this behaviour. The Nictation behaviour, when the worm stands on its tail and waves its head in three dimensions, is reproduced by stimulating six different neurons and evaluating the response of twelve motor neurons associated with head muscles. Each scenario simulated produces a dataset with the input currents used for stimulation and the voltage variations in time of the output neurons. By using different signals for the input currents, we are able to generate 40 diverse examples for each dataset. We further create completely equation-free data-driven models assuming no prior knowledge of the original system's structure and equations, using sequential neural networks trained on this data. For each scenario, we use 20 examples to train the neural networks models, 10 for validation and 10 for testing.

The models are generated using Recurrent Neural Networks (RNNs), first proposed in their simplest form in the 1980s to model sequential data [4, 5, 6]. Later, maintaining the same structure of the network, to better model long term dependencies, the Long Short-Term Memory (LSTM) unit was introduced [7, 8], with three gates used to remember past data and filter input and output information. In 2014 the Gated Recurrent Unit (GRU), consisting only of two gates with the same functions, was suggested to reduce the complexity of the LSTM unit [9]. These three different architectures are commonly used to model sequential data in tasks such as predicting energy demands, process monitoring or even machine translation.

RESULTS AND DISCUSSION

The three different flavours of Recurrent Neural Networks were trained on each of the two datasets, then tested and compared in terms of their properties and ability to model the *C. elegans* system response to diverse stimuli. The LSTM and GRU units proved able to accurately reproduce the system's response in both scenarios, producing significantly superior results when compared to the simple RNN unit. In Figure 1 we show the Root Mean Square Error (RMSE) over the number of epochs for the FCM scenario, computed in

the interest of fairness for the RNN with 16 units in the recurrent layer (404 parameters) and LSTM and GRU with 8 units in the recurrent layer (452 and 348 parameters). Examples of the predicted output voltage of the LSTM and GRU units on previously unseen data even with a modest recurrent layer of 8 neurons are shown in Figure 2. The examples shown are selected randomly from the test set, the prediction behaves quite similarly for the rest. Due to its simplicity, the GRU is preferable and was able to reproduce the original model's responses with an acceptable RMSE even with a hidden size as small as 4 units.

The LSTM and GRU units were further trained to produce a single model using both datasets, each unit generating a model able to predict the system's response on both the FCM and the NIC behaviours with low RMSE. These models were tested for previously unseen data, proving able to produce promising results with a small recurrent layer of eight neurons (as already done for each of the behaviours individually). The results show that it is

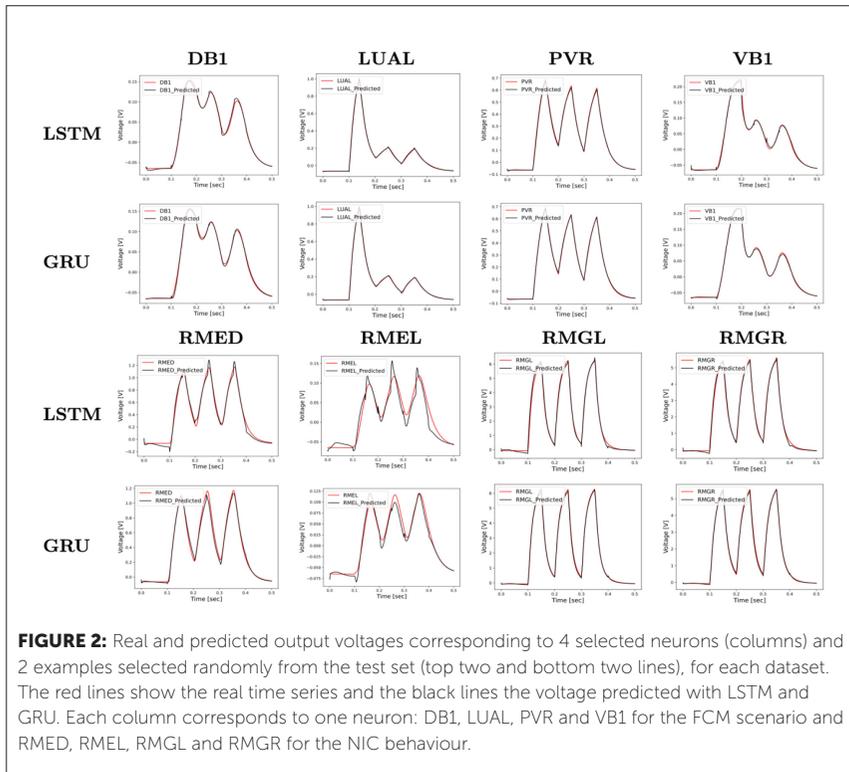

FIGURE 2: Real and predicted output voltages corresponding to 4 selected neurons (columns) and 2 examples selected randomly from the test set (top two and bottom two), for each dataset. The red lines show the real time series and the black lines the voltage predicted with LSTM and GRU. Each column corresponds to one neuron: DB1, LUAL, PVR and VB1 for the FCM scenario and RMED, RMEL, RMGL and RMGR for the NIC behaviour.

feasible to develop Recurrent Neural Network models able to infer input-output behaviours of real biological systems, even in the absence of a detailed level of connectivity.

INTRODUCTION/MOTIVATION

There are two points of view on the large-scale spatial dynamics of spontaneous and evoked EEG and MEG activity. The intra-cortical hypothesis assumes the propagation of traveling waves [1] in the cortex on a meso-scale due to intra-cortical axons (velocity < 1.0 m/s, 0.2 m/s characteristic speed). This propagation results in rotating electric dipoles that are projected onto the scalp, giving rise to the large-scale wave dynamics. The other point of view (namely, cortico-cortical hypothesis) assumes the propagation of large-scale waves due to cortico-cortical axons (velocity > 1.0 m/s, 6 m/s characteristic speed) [2]. The latter wave speed is observed in EEG, MEG and ECoG, but is not confirmed by direct recording (using intracortical microelectrodes or Utah arrays). Previously, we tested the validity of the above two approaches and showed a significantly higher-level correlation of the MEG experimental data by the results obtained using the meso-scale model [3]. However, a close look at the meso-scale model showed that the initiation of traveling waves could be related to the structure of the connectome.

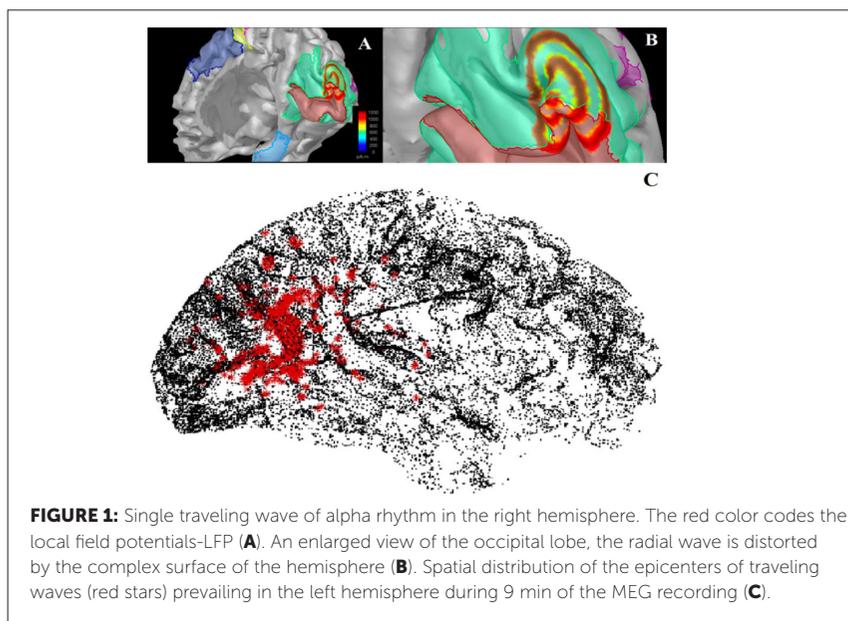

METHODS

For the MEG analysis, we used one healthy right-handed subject. The registration was carried out with a 306-channel MEG. The MEG recording had been carrying out for 9 minutes in the state of quiet wakefulness with closed eyes. A high-resolution structural MRI of the head was obtained using 3T tomograph. Based on the MRI data, a model of individual surfaces of the head and brain with the resolution of about 300 000 vertices was built. Each vertex was assigned to be an epicenter, for which the distributions of the current density in the form of radial traveling waves with propagation velocities of 0.2 m/s

(distances of 2 cm) and an average frequency of 11 Hz were calculated. We used radial traveling waves for simulation, since they are typically observed in recordings by microelectrodes and by optical methods in animals [1], and also by the Utah multielectrode arrays in humans [5]. The forward MEG problem was solved using the BEM separately for each hemisphere in the Brainstorm software environment. The model MEGs were compared with the experimental data by calculating two-dimensional correlation each time shifting the analysis window by 2 ms. The technique is described in detail in our previous works [4].

RESULTS

As an example, we demonstrate a reconstructed traveling wave of the alpha rhythm with an epicenter located in the central part of the retinotopic projection at $r > 0.7$, $p < 0.001$ the border of fields V1 and V2 (highlighted in purple and green, respectively) at rest with the eyes closed (Fig. 1A, B). Analysis of the 9-minute of MEG segment made it possible to identify a multitude of epicenters of such waves in the calcarine and parieto-occipital sulci (in the primary and secondary fields of the visual cortex). The epicenters were located chaotically, but strictly in the fields V1 and V2 of the cortex at $r > 0.8$, $p < 0.005$ (Fig. 1C).

CONCLUSION

Our previous study comparing two traveling wave models showed an unexpected effect of jumps in the epicenters of the traveling wave [3]. These results are in good agreement with the data on the dynamics of traveling waves in the human brain [5]. Alpha waves are specific to the visual cortex, and we previously considered their epicenters to be relatively stable [6]. The new result shows that, like saccades, when viewing images, there are changes in the position of the traveling waves epicenters in the visual cortex. The scale of traveling waves propagation we confirmed is comparable to the spatial dimension of the resting state networks, and we can assume the role of traveling waves in the local synchronization of such networks. Macroscale traveling waves are explained by the spatial dynamics of mesoscale cortical waves due to intracortical interactions. In turn, the role of connections between the visual cortex and the thalamus, which are part of the connectome, in the emergence of the alpha rhythm is well known [7]. In addition, these waves can be originated by cortico-cortical connections that are elements of the connectome. Thus, we assume that cortical traveling waves of the alpha rhythm are initiated by the connectome [8] and, of course, should be considered as one of the important elements of large-scale brain models.

ACKNOWLEDGEMENTS

We would like to thank the management and staff of the Moscow MEG Center for the opportunity for registration.

The reported study was funded by RFBR, project number 20-015-00475.

INTRODUCTION/MOTIVATION

In stroke, localized lesions lead to an acute loss of excitation to distant cortical regions and to significant disruptions in functional connectivity (FC), spreading beyond lesion vicinity, a phenomenon known as diaschisis [1]. During recovery, FC network properties are often recovered to nearly healthy levels through functional reorganization [2], [3]. However, it is not clear how the brain orchestrates this process globally, given the localized nature of lesions. Further, the process of recovery is accompanied by widespread changes in excitability [4], [5] that closely resemble synaptic scaling [6]. Therefore, we propose that local excitatory-inhibitory (EI) homeostasis, occurring through synaptic scaling, may play an essential role in the recovery of global network properties of stroke patients. We aim to understand how to tie the local and global scales in stroke recovery, essential for improving the prediction of future deficits and informing targeted rehabilitation techniques that maximize the potential of recovery.

METHODS

To model large-scale cortical activity, we used a network of nodes constrained by human structural connectivity data, simulating the activity of individual regions with Wilson-Cowan coupled EI populations (Fig. 1A). Homeostatic

plasticity was implemented through a plasticity rule that adjusts the weight of local inhibitory connections according to presynaptic activity and the deviation of postsynaptic activity from a target, as in synaptic scaling (Fig. 1B). Lesions were simulated by removing all the connections to and from a single node and model activity was extracted pre-lesion (T_0), post-lesion (T_1) and post-lesion after stabilization of inhibitory weights (T_2) (Fig. 1C). Lesion effects were measured through changes in FC graph properties representing

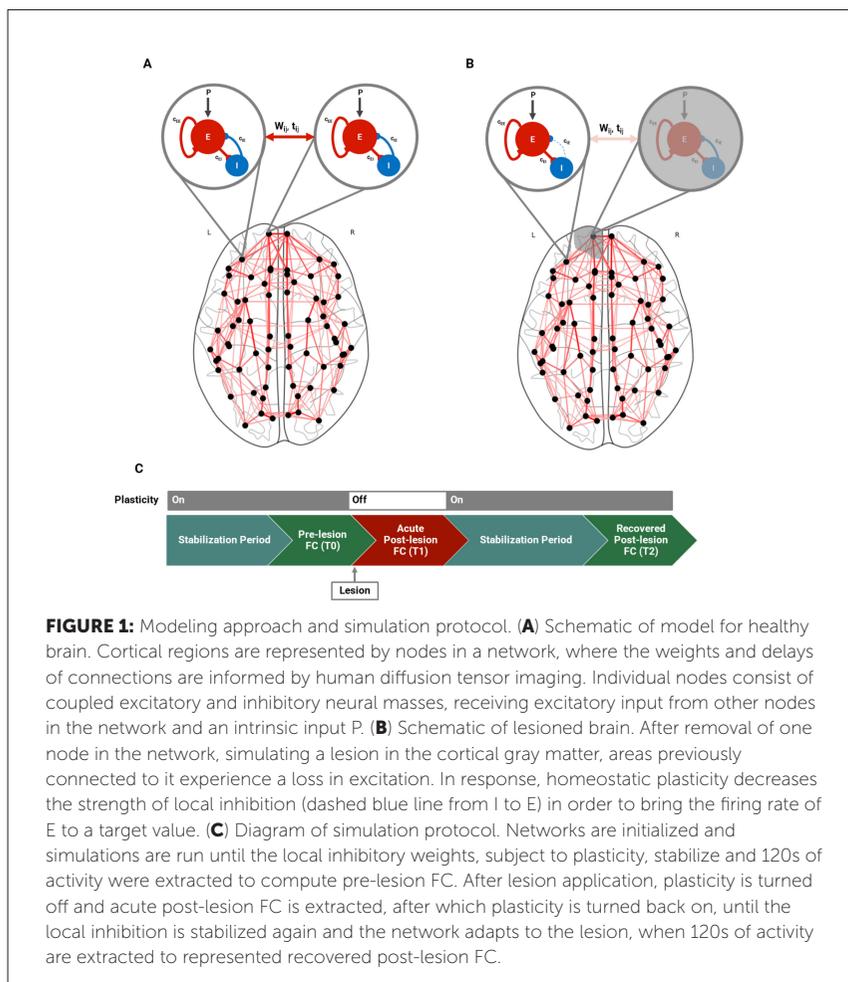

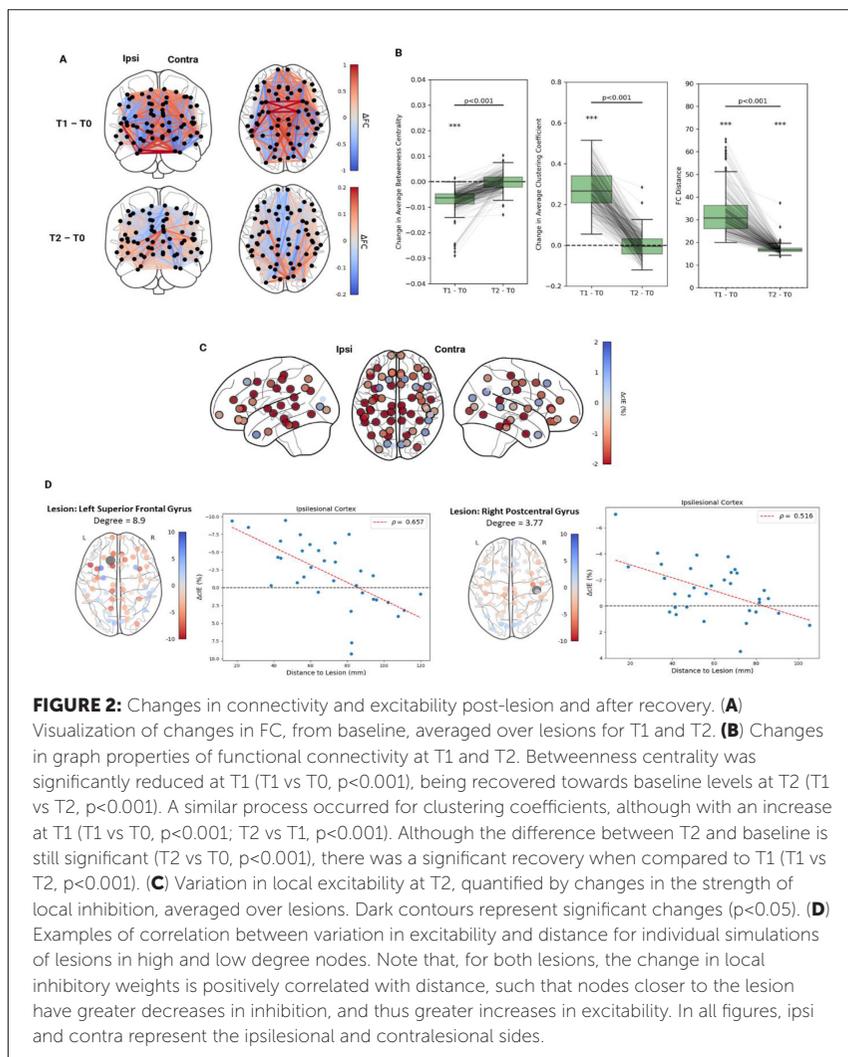

FIGURE 1: Modeling approach and simulation protocol. **(A)** Schematic of model for healthy brain. Cortical regions are represented by nodes in a network, where the weights and delays of connections are informed by human diffusion tensor imaging. Individual nodes consist of coupled excitatory and inhibitory neural masses, receiving excitatory input from other nodes in the network and an intrinsic input P. **(B)** Schematic of lesioned brain. After removal of one node in the network, simulating a lesion in the cortical gray matter, areas previously connected to it experience a loss in excitation. In response, homeostatic plasticity decreases the strength of local inhibition (dashed blue line from I to E) in order to bring the firing rate of E to a target value. **(C)** Diagram of simulation protocol. Networks are initialized and simulations are run until the local inhibitory weights, subject to plasticity, stabilize and 120s of activity were extracted to compute pre-lesion FC. After lesion application, plasticity is turned off and acute post-lesion FC is extracted, after which plasticity is turned back on, until the local inhibition is stabilized again and the network adapts to the lesion, when 120s of activity are extracted to represent recovered post-lesion FC.

segregation (average clustering coefficient, CC) and integration (global efficiency, GE), and FC distance (FCD). Changes in excitability were quantified by differences in local inhibitory-to-excitatory weights between T1/T2 and T0, representing changes in GABAergic transmission.

RESULTS AND DISCUSSION

As in previous literature [2], [3], results showed increased CC (0.162 ± 0.041 , $p < 0.001$) and decreased GE (-0.068 ± 0.067 , $p < 0.001$) at T1, indicating more segregation and less integration between cortical areas. Both metrics were globally recovered towards baseline levels at T2 ($p < 0.001$ for both) through the action of local EI homeostatic mechanisms (Fig. 2A,B). Furthermore, while FCD at T1 was strongly dependent on the strength of the lesion node ($\rho = 0.85$), correlations at T2 were weaker ($\rho = 0.33$), indicating a lesser dependence of recovery on the properties of lesioned areas, being more reliant on the ability of the brain to restore balance, indicating an important role of EI homeostasis in stroke recovery. The connectivity within and between resting-state networks was also evaluated at T2, showing a complex pattern of widespread reorganization (e.g. decreased internal connectivity in default mode network). Furthermore, changes in excitability in individual regions could be moderately predicted from structural connectivity of said regions with lesioned nodes ($\rho = 0.47$) and, similarly to previous research [5], the magnitude of changes decreased with distance from the lesion in individual simulations (Fig. 2D). Looking at variations in excitability across simulations (Fig. 2C), we observed significant widespread increases (56 regions out of 68), fitting results from rodent models [5] and human patients [4]. Surprisingly, a tendency to experience decreases in excitability in particular cortical areas, mainly the superior frontal gyrus, temporal pole and cuneus, could be responsible for the increased propensity of patients to develop late-onset symptoms (e.g. depression) [7], previously linked to decreased excitability in the same regions.

INTRODUCTION/MOTIVATION

Robots working in manufacturing must be adaptive, due to the dynamic manufacturing processes. They need to be able to spontaneously adapt to their environment and avoid obstacles online, which requires a fast and flexible planning algorithm, to enable Human-robot collaboration. However, the complexity for such a calculation increases significantly for high degree-of-freedom (DOF) robots. Inspired by the excellent sense of orientation of mammals, researchers [1], imitated the presumed virtual map made from so-called place cells in the hippocampus, using Spiking Neural Networks (SNNs). In [1] and [2] a neural Wavefront Algorithm (WFA), realizing path planning as a breadth-first search, is executed on a grid of place cells represented by an SNN. Due to learning via Spike Timing Dependent Plasticity (STDP), synapses on a path between target and start position are strengthened. The 2D approach for mobile robots introduced in [1] got expanded to 3D by [2] which both have shown to be executable in reasonable time. However, robotic path planning must not only deal with a single point, as which the TCP can be understood as the focus of a task, but all joints regarding collision avoidance and energy efficient paths must be considered primarily. The goal of this work is to design a collision-free path planner for industrial robot arms with 6 DOF. Due to the demanding time requirement of the required online planning, a SNN based path finding technique based on the mechanics of place cells is used. A planning that takes place exclusively in the configuration space of the robot is discarded to avoid the complexities of a high dimensional search space.

METHODS

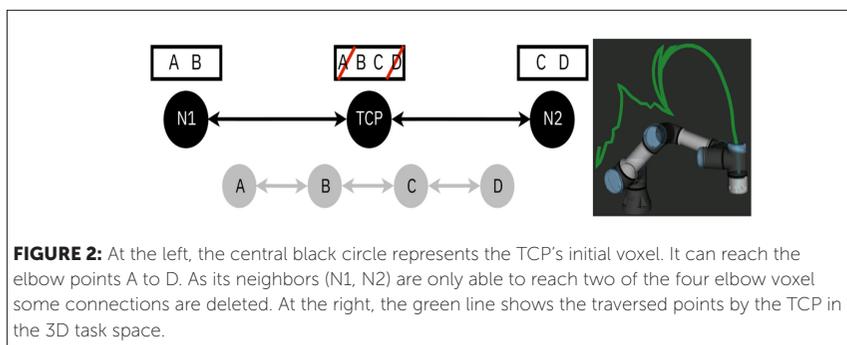

To represent the 6D configuration space (C-space) of an industrial robot with 6 DOF two separate neural networks are created as visualized in Figure 1. The first represents the elbow of the robot and depicts a map in its 2D C-space, depending on the first two relevant robot joints. The second symbolizes the TCP's task space in 3D.

Hebbian learning, a common paradigm of synaptic plasticity, embodies two factors, the income of pre-synaptic and the creation of post-synaptic spikes. However, Hebbian learning merely makes a synapse receptive, a third factor is needed to transform synaptic plasticity into learning in form of weight change [3] The so called three-factor rule influences synaptic plasticity with a neuromodulator.

Path planning in a high dimensional C-space holds computationally intensive elements. First of all, the calculation of the inverse kinematic (IK) to get an appropriate configuration for a large number of positions. But also finding all reachable points in the complementary voxel grid is too complex to be done online while the robot is moving. Therefore, the approach is separated into two parts. The first part takes place purely offline and consists of the majority of all necessary complex computations, which are then stored in a LUT. Thereby the position in the Cartesian and the C-space as well as the weighted connections of all neurons in both networks are calculated and stored. During the actual online planning, it is then only necessary to plan between these known points. The LUT, represents the neuromodulator of the three-factor rule for our learning process. The planner's second stage, the WFA, is performed online after using the previously saved information to create the two SNNs that are simulated with Nengo [4].

During the online planning, firstly a WFA is initiated in SNN 1 (elbow). Subsequently, the synapses of the SNN2 (TCP) are adapted before a second WFA is applied within that network. The synaptic adaptations between the two consecutive neural WFA guarantee valid movement options later on. In Figure 2 it is visualized which network combinations generate unfeasible trajectories and are thus deleted. As the WFA alters the synaptic weights by STDP, for each node a synaptic vector can be calculated. These vectors are considered forces propelling an agent through the network.

RESULTS AND DISCUSSION

The resulting robot motion is simulated using the MoveIt framework, with ROS2. For all experiments a simulated UR3 e-series robot shown in Figure 1 & 2 is used. It was shown that two WFA in two SNN can be applied for motion planning of a 6 DOF robot. The performance results of a separated analysis of the on- and offline parts show that creating a LUT in a time-uncritical environment was very helpful. The time required to calculate the IK and create and link the two networks takes hours, depending on the size of both networks which contradicts the requirements to be fast and flexible. However, this effort is only required once per robot and workspace and can then be used to significantly reduce the time required for the online calculation of a path.

Generally, the results, as visualized in Figure 2, show that collision-free paths cannot be guaranteed. The coverage of the 6D C-space in 3D is not sufficient, why some configurations do not exist in the networks. This results in planning tasks being traversed very extensively and also configurations with a large 6D distance for two points adjacent to each other in the Cartesian task space. To overcome this distance, linear interpolation is currently used. Nevertheless, there is great potential in splitting into two networks of manageable dimensions. Also precomputing and storing potential network connections in a LUT, can circumvent the problematics of 6D planning in general. As one weakness is the implementation of the link between the two SNNs, future work focusses on improving the C-space's mapping to the task space of the TCP. Finally, the SNN simulation will be applied on neuromorphic hardware.

INTRODUCTION/MOTIVATION

Psychological theories and experiments on animal learning through conditioning and reward mechanisms have strongly influenced reinforcement learning (RL) for artificial agents [1]. By merging these psychological insights with neuroscience and robotics, RL enables new perspectives on multiple scientific fields. To facilitate this kind of interdisciplinary research, we tackle a robotic reaching task with RL using a 6-degrees-of-freedom HoLLiE robot arm [2] simulated in the Neurorobotics Platform (NRP) (Fig. 1) [3]. The goal of the reaching task is to find a valid motion trajectory for a robot's end effector to reach a predefined target position in 3D space by maximizing a reward function.

Our main contributions are a self-contained simulation-based RL environment in the NRP for rapid prototyping and scalable RL experiments using docker, and a comprehensive study comparing different state-of-the-art RL algorithms, using different state representations, network architectures, learning mechanisms and reward types, under different levels of difficulty of the reaching task. Both the environment and code are available online.

METHODS

The simulation environment is shown in Fig. 1. The agent completes the reaching task in an episode by moving the end effector, from its initial pose within a predefined proximity of the target position using a single movement, based on the ground truth (GT) target position or the image data. A camera

looks down at the table from above when learning from image data. The agent's decisions are based on a state space vector which includes the end effector position, joint angles, and GT cylinder position or image information. Our experiments investigate sparse and dense reward functions and action space variations with three, four, or six active joints. The sparse reward function only rewards the task completion (overstepping a proximity threshold). The dense reward function encourages movements in the right direction. We compared two model-free, actor-critic architecture-based algorithms: Twin Delayed Deep Deterministic Policy Gradient (TD3) [4] and Soft Actor Critic (SAC) [5]. A video demonstration showing the setup and some of the experiment results is available.

When **learning from GT** data, the agent's task is to find an approximation for the inverse kinematics – which set of joint angles correspond to a given end effector location in the Cartesian space. We distinguished between models trained with TD3 and SAC, incorporation or exclusion of hindsight experience replay (HER) [7], dense or sparse reward functions, and the number of

actuated joints (Table 1). HER improves learning efficiency by reinterpreting unsuccessful experiences in achieving a particular goal into successful ones by adapting the goal to the result of the chosen action.

When **learning from images**, we can either extract the GT data, extract a latent space representation, or directly feed the images as input to the agents. The GT extraction benefits from reusing the previously trained models and reducing computational time since processing high-dimensional data is expensive. On the downside, such a pre-processing step is rigid and shows poor cross-domain generalization. To predict the position of the cylinder, we implemented a classical computer vision (CV) and a CNN-based approach. The former isolates the cylinder by subtracting an averaged image mask, applying a threshold, and transforming the extracted image coordinates to simulation coordinates. The latter uses a shallow model with two output logits that we pre-trained on CIFAR10 [8]. The latent space approach aims to derive a low-dimensional representation that encodes the most meaningful features of the image, including the cylinder position. However, the small variation in our data makes it difficult to train such a model, motivating the use of transfer learning in further work.

We trained all models using threshold scheduling as a curriculum learning approach. In this process, all models started with an initial threshold of 20 cm. The threshold was then progressively reduced whenever the model reached a specified performance level.

RESULTS AND DISCUSSION

Table 1 contains the evaluation results of our different model configurations. When learning from GT, our best performing three-joint and four-joint TD3 models use dense rewards and HER. The four-joint model is the most successful TD3 model, with an average distance to the target of 2.4 cm. Interestingly, the six-joint agent cannot compete with the four-joint agent. This reflects how complexity increases exponentially with the state space dimensionality.

Regarding the SAC models, the most successful three- and four-joint configuration used sparse rewards and no HER. In turn, the less constrained six-joint SAC model benefited from HER (Table 1). The fact that HER led to a drop in performance for the first two cases was unexpected and stood in direct contrast to the three- and four-joint TD3 models. It indicates that our

Table 1: Evaluation of the RL algorithms. The threshold is the minimum proximity of the robot end effector to the target in order to consider an episode successful. The actuated joints show which joints could be used by the agent to solve the reaching task.

^cLearning from images: manual extraction

^dLearning from images: CNN extraction

constrained action spaces already ensure a high enough sampling efficiency for SAC. Despite relatively short training time compared to the TD3 models, the six-joint SAC model reached an average distance of 2.1 cm and thus represents our overall best model.

When learning from images, we used our best performing TD3 model with the manual and CNN extraction pipeline, respectively (Table 1 below dashed line). Both methods extracted the target position with an average error of ~2 cm. Overall, the CNN extraction method showed slightly better performance with an average distance of 5.6 cm.

In future work, we want to approach the same task using RL and Spiking Neural Networks and compare their performance to the Artificial Neural Network models used here.

INTRODUCTION/MOTIVATION

Reaching a target is one of the most important tasks in robotics – object interaction, manipulation and grasping tasks require moving the arm to specific targets [1]. However, there are many models of industrial robotic arms. They have different kinematics and hardware components. The robotic arms usually have different controllers depending on the manufacturer. In addition, each application developer will add different sensors for their setup.

This is problematic because there is no unified and understandable way of controlling multiple robots, which makes it difficult to port controllers between systems. In this work, we show how the same control strategy can be used with four different robot arms in the Neurorobotics Platform (NRP) [2][3]. This work extends the work presented in [4][5] of motor control for target reaching using motor primitives with spiking neural networks (SNN) [6]. The same SNN is used for all robots, but the motor primitives are trained with corresponding trajectories for each robot. This approach is model free and does not require the calculation of the inverse kinematics or the validation of the configurations.

METHODS

In [4][5] an SNN for target reaching was presented (see Fig. 1). To model the motion in 3D, the work in [4][5] uses three motor primitives for the arm – left-right, up-down and far-near. The motions of the three motor primitives are combined using an error signal from the desired target. This method resembles characteristics of visual-servoing [7], but instead of using visual feedback, we use the ground truth position of the target in simulation. In this work we extend the work from [4][5] to control four different robotic arms.

The first step is to integrate the SNN for one robot implemented using Nengo [8] in the NRP. Then we define an experiment with four robotic arms in simulation – Kuka IIWA14, Schunk LWA4P, Panda and UR5e (see Fig. 2a). We extend the brain simulation of the NRP to use multiple brains, one for each robot. Which allows the use of an instance of the SNN for target reaching for each robot. Each of the SNNs is trained with three example trajectories of each robot – one for each primitive. We add transfer functions between each robot and each brain. We also added a state machine that generates targets for all the robots. The targets are represented as spheres, where the

center is the target, and the radius is the allowed error (see Fig. 2a). Each brain gets the corresponding feedback about its target. When the target changes the SNN of each robot generates control commands for each arm to reach the targets.

RESULTS AND DISCUSSION

As a benchmark task we defined an experiment where the state machine generates targets in the corners of a rectangle, so that the robots perform a trajectory across the edges of a hypothetical rectangle. Although, the SNNs for each robot have the same topology, the primitives are defined individually for each robot. This means that it is possible that different robots have different configurations for the same target as shown in Fig. 2a. The resulting trajectories are shown in Fig. 2b. The robots are different, with different sizes, and so the trajectories are not of the same size, and thus they are scaled accordingly. The similarity in the appearance of the motion can be observed. The target points for the rectangle are shown as red dots in Fig. 2b. The experiment shows that the SNN control strategy can be used to control different robots. Still, as it can be seen in the trajectories in Fig. 2b, there are control problems on the system as in [4][5]. This is happening because the raw spiking output of the network is being used for the control. This can be solved by using a low-level controller to smooth the control signal. This work presents an opportunity for porting a flexible control architecture with SNN to neuromorphic hardware such as SpiNNaker [9] or Loihi [10] and use it to control the real robots. The proposed experiment can be used as a benchmark for other control approaches with SNN and highlights the use of the NRP for this purpose.

INTRODUCTION/MOTIVATION

Simulation frameworks in computational neuroscience support the interdisciplinary study of the relationships between structure and dynamics in the brain integrating knowledge from different disciplines and reproducing functional features at multiple scales. These virtual spaces where researchers can model the brain, generate hypotheses and perform multiple experiments have become an essential tool to understand the brain in states of health and disease, as well as during development and aging [2]. Emerging computing infrastructures support the development and execution of such frameworks and allow for the simulation of detailed models. These models take into account a variety of features and variables related to the function of neurons, networks and brain regions.

The Virtual Brain enables simulation of the whole brain with advanced mathematical models in combination with empirical data such as Electroencephalography, Magnetoencephalography and Magnetic Resonance Imaging [3].

Translating the mathematical and abstract descriptions of brain models into efficient code is a task which requires specialized knowledge and experience. Whole brain simulations can also be tuned to fit the parameters of specific subjects [5] using experimental measurements from individual brain structures and dynamics [6]. This process is computationally intensive and requires scientists to explore vast combinations of parameters in their models.

†these authors contributed equally to the work

In order to ease the translation from differential equations to executable code and make computational infrastructure accessible to scientists with different backgrounds, we have designed a modelling framework which combines a domain specific language with an automatic code generator; called RateML. This allows us to detach modelling from software implementation, a technique which is becoming ever more common in computational neuroscience [7].

NestML [17], i.e., is a modelling tool which targets the description of point neuron models and synapses. NeuroML [18], which is used by Arbor [14], enables users to define single cells and network of these cells. Another modeling tool is NineML [15] which focuses on networks of point neurons. RateML focuses on modeling the dynamic variable of mesoscopic brain activity, identical to the models used by the TVB simulator. A modeling tool for TVB and TVB on HPC does not exist in this fashion.

METHODS

RateML builds on top of a domain specific language called 'Low Entropy Model Specification' (LEMS) [8], the language is not extended and can be used natively. With RateML users can formulate the differential equations which describe their models using an XML representation which is later used to produce Python and CUDA [9] code. With the CUDA code, end users can utilize the parallelization power of Graphic Processing Units (GPUs) in order to explore wide ranges of values for parameters specified in their models.

RateML is part of the main TVB repository¹. Documentation as well as blank model from which you can get started can be found in this repository. Next to this many existing TVB models have already been ported to RateML.

To use RateML and for instance generate a Python model which can be simulated with the TVB simulator, the user can start by opening the blank model from the repository and complete the *ComponentType derivatives*. This *ComponentType*, shown in Figure 1, has elements with which the behaviour of the users model can be defined. It consists of the elements: *Constant*, *Exposure*, *StateVariables* and *TimeDerivatives*. *Constants* are used to define the unmutable intrinsic characteristics of the model. The *Exposure* is used to

¹<https://github.com/the-virtual-brain/tvb-root.git>

```
1 <ComponentType name="derivatives">

12     <TimeDerivative variable="dV" value="omega + c_pop0"/>
13   </Dynamics>
14 </ComponentType>
```

FIGURE 1: XML derivatives definition for Python Kuramoto model.

define the to be monitored variable of the simulation, the *StateVariable* and *TimeDerivative* make up the dynamic behaviour of the model.

When the user is finished, she can run at the command line:

python XML2model.py --model kuramoto --language python

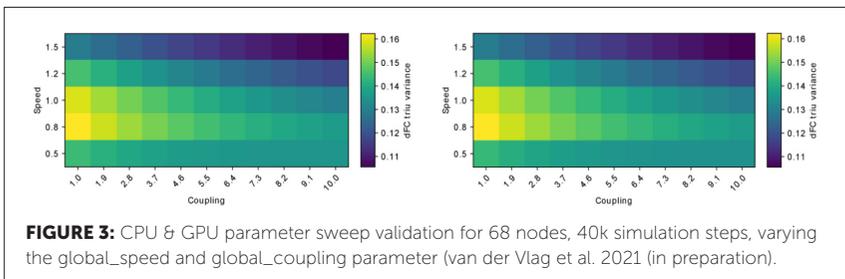

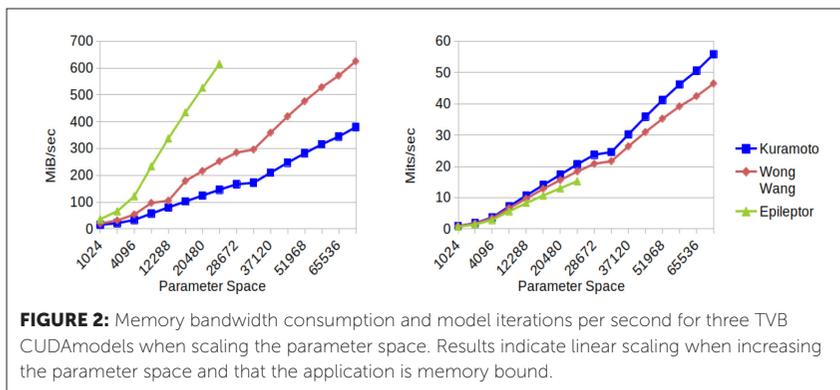

To generate a TVB model which will be familiarized by the her TVB installation directly. The user can immediately make a simulation with the generated model. She never has to see the resulting model file or has to worry about the performance of the underlying code; this has all been abstracted from the modeling effort.

The example in Figure 1 is for the Python backend. For the CUDA backend, two extra *ComponentTypes* have to be defined, namely for the *coupling* and *noise*. In the repository the user will find many example and Jupyter notebooks on how to generate the CUDA models.

RESULTS

We have implemented the RateML framework which is currently available as part of The Virtual Brain distribution. We have benchmarked simulations using three well known and widely used neuraml mass models from TVB: the Kuramoto [10], WongWang [11] and Epileptor [12].

The simulations used for the benchmarking were executed for 40,000 simulation steps, with a time step of 0.1 ms and using a deterministic Euler integration scheme. The number of parameters was increased in order to observe the changes in the execution time and memory usage by the different models. Figure 2 shows the results of the benchmarking, indicating how RateML is able to produce code which exploits the whole capacity of a GPU to enable explorations of thousands of parameters in parallel. All simulations were executed in the Booster partition of the JUWELS supercomputer in the Julich Supercomputing Centre. Each node in the JUWELS booster has 4 A100GPUs with 40 GB of memory.

To validate the RateML generated models, we used an existing experiment as a scaffold. The Montbrió [14] model was used in a study on the role which neuronal cascades play in the causation of whole-brain dynamics at rest [13]. RateML was used to input their models characteristics and produce a CUDA model and driver to mimick their results. This CUDA model was then compared against the TVB results for 5x10 of different parameter combinations. Figure 3 shows the results when comparing the CUDA and the TVB results. The error is smaller than $13.4e-5*t$, in relation to the timestep, proving that the generated model is suited and accurate to use for such experiments.

DISCUSSION

In conclusion, RateML offers the neuroscience community with a new tool to automatically generate code from abstract model representations, enabling easy computing with Python as well as access to the full power of GPUs for parameter exploration. RateML allows the modeling of brain neural models and Neural Mass Models in a simple way, detaching the optimized implementations from the modeling and simulation infrastructure. RateML supports the investigation and generation of new models to study the links between structure and function in the brain enabling also a thorough investigation of the link between specific model parameters and the dynamics produced.

INTRODUCTION/MOTIVATION

Our brains are able to efficiently process and learn from the vast amount of information our senses provide about our environment. Understanding the computational principles underlying this unparalleled computational capacity is not only important for basic neuroscience research but also for advancing artificial intelligence. Neuromorphic engineering in particular tries to replicate the brain's fundamental principles in new novel hardware to overcome the constraints, for example high energy consumption, present in classical von Neumann architectures. Conversely, error backpropagation [1], the basis of deep learning algorithms, can serve as inspiration to neuroscientific models about how complex tasks may be learned in the brain. However, naive implementations of backpropagation are at odds with neurobiology [2]. Thus, there is an effort in the field of computational neuroscience to devise models that leverage the strength of credit assignment via backpropagation in a biologically plausible way [3,4,5,6]. One approximation of backpropagation which incorporates constraints from biological systems, developed by Sacramento et al. [4], consists of a hierarchical architecture of microcircuits composed of multicompartiment inter- and pyramidal neurons. In particular, unlike classical deep learning models, this model does not rely on separate forward and backward phases, avoids the weight transport problem by using random feedback weights, and the learning of synaptic weights relies on a local, plausible plasticity model [7]. In this study we aim to make the model by Sacramento et al. compatible with a range of neuromorphic hardware platforms [8,9,10] by moving from a rate-based to a spike-based implementation. We demonstrate in software simulations that our modified spiking version of the model preserves the functional principles allowing the original rate based model to learn.

We modified the original model to make it suitable for emulation on multiple different neuromorphic substrates. One common ground for most platforms is their ability to emulate Leaky Integrate-and-Fire (LIF) neurons [11]. We replace the apical compartments in the original model with LIF point neurons and combine the somatic and basal compartments into a single LIF neuron (Figure 1B). The error in the apical compartment, which was previously represented as a voltage, is now encoded using spikes. To enable the encoding of negative error values, neurons fire with baseline activities and errors are represented as deviations from this baseline. In the original model, activity was communicated in the form of instantaneous firing rates, a non-linear function of the somatic voltage. Now communication between all neurons is spike-based. As in the original model the plasticity of the synapses is driven by applying the Urbancik Senn learning rule [7] on the neuronal firing rates, computed from the spike counts over the duration of each sample presentation. For the software simulations of the model we chose the PyNN library [12] with NEST [13] as a simulation backend. While the model could have been implemented using other libraries such as Brian [14] or PyNEST [15] or GeNN [16], PyNN was chosen as it can also operate as a frontend for the neuromorphic platforms BrainScaleS 2 [8] and SpiNNaker [9].

RESULTS AND DISCUSSION

To test whether the basic principles of the original model were unchanged by the previously explained modifications, we performed software simulations of a simple nonlinear regression task using a single microcircuit (Figure 1B). The network of LIF neurons was able to learn simple input-output pairs (Figure 2A-D). Furthermore, the errors, represented by the activity of the “apical” error neurons in both the hidden and output layer, drive learning and decay to their respective baselines when the output approaches the target (Figure 2E). Even though our model relies on fundamentally different single-neuron dynamics and employs spike-based communication, we preserved the fundamental principles underlying learning in the original model.

Further work will focus on implementing the modified model on current spiking neuromorphic platforms such as the digital SpiNNaker system [9] and the mixed-signal BrainScaleS 2 system [8]. By having both learning and inference fully embedded in the same neuromorphic substrate we hope to make full use of the speed and energy efficiency of these brain-inspired architectures.

INTRODUCTION/MOTIVATION

Surrogate spike train data is used to generate the null hypothesis in the context of the significance analysis of spike train correlations and spatio-temporal spike patterns. In our work, we compare five different surrogate techniques against the classical technique called Uniform Dithering (UD [1]). In particular, we discuss the use of the surrogates to generate the null-hypothesis distribution in the statistical test of the SPADE method (Spike PAttern Detection and Evaluation [2,3]), which detects spatio-temporal spike patterns in parallel spike trains. In SPADE, both spike trains and surrogate realizations are discretized into 0-1 sequences (binarization) before the pattern detection. We discover that binarized surrogates have a lower spike count than the original data, due to the change in the surrogate's inter-spike interval (ISI) distribution caused by the UD algorithm. The spike count mismatch between the original data and the surrogates is predominant in the case of high firing rates, spiking regularity, and presence of a dead time (minimal temporal distance between spikes typically induced by spike sorting). We prove that spike count reduction leads to false positive (FP) detection, motivating us to explore alternative surrogate techniques to UD.

METHODS

Surrogate Techniques (Figure 1)

- Uniform Dithering (UD)[1] displaces each spike individually according to a uniform distribution.
- To account for the dead-time present in experimental data, Uniform Dithering with Dead-Time (UDD) limits the displacement of each spike such that the dead-times are conserved.
- (Joint)-ISI dithering [4] displaces each spike individually preserving the (joint-) ISI distribution.
- Window Shuffling shuffles binarized spike trains inside of short windows.
- Trial Shifting consists in shifting entire segments of a spike train according to a uniform distribution, independently trial by trial, and neuron by neuron [1, 5].

SPADE

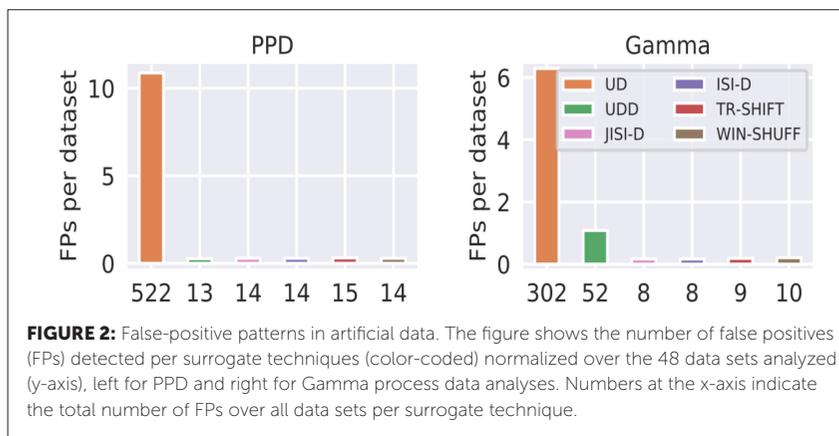

SPADE detects spike patterns at a millisecond resolution, allowing for temporal delays between the spikes. The spike trains are first discretized and patterns are then mined and counted. To assess the significance of these patterns, the same procedure is performed on multiple realizations of surrogate spike trains, resulting in a p-value spectrum [3]. Significant patterns have p-values lower than the (corrected) significance threshold.

Artificial data generation

In order to evaluate the effect of the different surrogates on SPADE, we create artificial spike trains modeled according to the statistics of experimental data from the pre-/motor cortex of macaque monkeys [6], including non-stationary firing rate profiles. The dead time and regularity of the data are modeled by simulating Poisson processes with dead-time (PPD) and Gamma spike trains, respectively. In particular, using a Gamma process the coefficient of variation can be adjusted explicitly, thus allowing for the generation of regular and bursty processes.

RESULTS AND DISCUSSION

We observe that UD surrogates modify the ISI distribution of PPD and Gamma spike trains (approximately) into an exponential distribution. As a consequence, spike counts are reduced after binarization. By applying SPADE on the artificially generated data, we observe a high number of false positives when employing UD (see Figure 2). Thus, we conclude that UD is not a suitable surrogate technique for spike train data that either contains a dead-time or is regular. The alternative surrogate methods, instead, yield a consistently low number of false-positive patterns; between 8 and 15 FPs in 48 analyzed datasets (except for UDD on Gamma spike trains). In conclusion, since trial shifting is the simplest method among the best-performing ones, we recommend it as the method of choice.

INTRODUCTION/MOTIVATION

Hearing loss is a heterogeneous disease that affects about 5% of the world population [1]. Given the central nervous system's plasticity during the maturation period and congenital deaf individuals' visual dependence to interact with the environment, reorganization within intact sensory modalities is expected, especially in vision [2,3]. Compensatory changes resulting from deafness have been reported, particularly the improvement of peripheral visual attention capability [4,5,6]. In terms of behaviour, greater speed and accuracy in detecting peripheral stimuli (visual target) is described, and, in terms of electroencephalography (EEG), a more pronounced desynchronization of the alpha and beta band is associated with attention [7,8,9,10,13,15]. In this sense, we aimed to verify whether there are significant changes in visual attention capability between individuals with congenital or early deafness and individuals with normal hearing.

METHODS

This study was experimental, cross-sectional and descriptive. The participants were divided into the experimental group (congenital or early deafness), constituted by 4 participants, and control group (no auditory deficit), constituted by 7 participants. Each participant completed a selective attention task resorting to the immersive virtual reality equipment HTC vive, with

simultaneous recording of electroencephalographic activity in the parietal and occipital areas using the Biopac System MP36. The selective attention task consisted of a set of objects arranged in a circle. The target object appears in one of the positions of the circle and, inside or outside the circle, appears a second object, the distraction (Figure 1). The levels increase in difficulty when the target and the distraction are incongruent (different objects) and when the fill-in objects are congruent with the target/distraction (same color). The goal of the attention task is to identify which target is present (iogurt or coca-cola). Participants were instructed to ignore the distraction and identify the target as quickly and accurately as possible.

The procedure consisted of a rest period, in which an EEG recording was performed with the participant sitting comfortably, and a study period that corresponded to the EEG recording during the performance of the attention task. The EEG component was analyzed using the AcqKnowledge 5.0 software, in which we used the EEG Frequency Analyzes algorithm to obtain the power of the alpha band frequency. In the behavioral component, reaction time and response (correct or incorrect) were analyzed. Statistical analysis

was performed using the Statistical Package for Social Sciences (SPSS) 27 and Microsoft Excel 16.52 software.

RESULTS

A decrease in the alpha frequency power between before and during the attention task was observed in the electroencephalographic component. This decrease happened in both groups in the parietal region (experimental $p = 0,125$; control $p = 0,286$) and in the occipital region (experimental $p = 0,080$; control and $p = 0,362$). When comparing this decrease between both groups there was a statistically significant difference in the occipital region ($p = 0,038$), more prominent in deaf individuals. Despite not being statistically significant, the remaining electroencephalographic results also suggest a more considerable decrease in the alpha frequency power in the experimental group. In the behavioural component, the same was verified; although there was no statistically significant difference between the experimental and control groups, the results point to greater visual attention in the experimental group. When comparing the reaction time with the peripheral distraction between both groups we obtained a faster response in the experimental group ($p = 0,088$), the same was verified with the central distraction ($p = 0,798$).

DISCUSSION

This study was conducted during the COVID-19 pandemic. As a result, one of the most significant limitations we were met with was recruiting volunteers, particularly for the experimental group. Thus, the fact that most of the results found are not statistically significant is most likely due to the sample size, mainly in the experimental group. The electroencephalographic result obtained in the occipital region indicates a higher desynchronization in deaf individuals, which points to a higher visual attention [14,16]. The remaining results, in spite of not being statistically significant, suggest a higher visual attention capacity in deaf individuals as well [11,12]. Therefore, it is essential to carry out new investigations to overcome the limitations in this study, especially the sample size. It should be noted that the investigations focusing on the deaf community are a tool for their inclusion in society as they provide relevant information for the development of new teaching methods and vocational approaches valuing their capabilities, despite their limitations.

INTRODUCTION/MOTIVATION

Working memory (WM) is the core cognitive phenomenon, which affects everyday life (Baddeley, 2010). It was shown that WM relies on several brain regions, however, the core areas were proposed to be frontal and parietal (Owen et al., 2005; Chein et al., 2011), which both constitute the frontoparietal network (FPN). The activity of FPN determines working memory capacity (WMC), which serves as a predictor of future academic success (Unsworth, Heitz, Schrock & Engle, 2005) and is usually a target for scientists attempting to increase capacity. One of the most promising tool to enhance WMC is transcranial direct current stimulation (tDCS). A large number of studies were conducted with this neurotechnique, however, their effect on WMC remains contradictory (Hill, Fitzgerald & Hoy, 2016). Moreover, no studies investigate the effect of simultaneous stimulation of both components of the frontoparietal network. Because of the inconsistency of tDCS results and lack of data about the effect of simultaneous stimulation of both frontal and parietal areas during working memory functioning, we conducted a study, where we compared the performance of working memory task for the groups with no stimulation, stimulation of one FPC component and both.

METHODS

We used tDCS to influence the performance during the operation span task. Forty-five participants were equally split into three stimulation groups: with simultaneous anodal stimulation of P3 and F3 brain areas (double stimulation

group) according to the 10/20 EEG system (Lagerlund et al., 1993), with anodal stimulation of only F3 area (single group) and with sham stimulation. We calculated with power analysis that 45 participants will be enough for the between-group design. The stimulation lasted fifteen minutes. After it, participants performed an operation span – complex working memory task, where respondents have to memorize a set of letters while simultaneously verifying mathematical equations (Turner & Engle, 1989). This task was shown to reveal good validity and reliability rates (Klein & Fiss, 1999) and allows precise measurement of domain-general WMC. We analyzed the effect of stimulation type on memory performance measured traditionally with mathematical accuracy inside it (Conway et al, 2005), to memory and mathematics separately, and to response time (time of calculation and time of recall). We considered separate results of memory and math in order to reveal a potential attentional bias to one of the tasks due to stimulation. Memory performance was calculated as partial credit scoring (PCS – the average ratio of correctly recalled items) and partial credit load scoring (PCLS – the average number of correctly recalled items). We applied one-way (between-group factor – stimulation type) and two-way (between-group factors – stimulation type and span size) ANOVA to reveal any possible effects. We hypothesized that stimulation of only one component of FPN will increase WMC in comparison to sham stimulation. The stimulation of the second component will increase WMC significantly higher in comparison to both single and sham groups, which will indicate that the two components of FPN are functioning as separate units.

RESULTS

There was no difference in mathematical accuracy (Fig. 1) and time of calculation among the three groups (Fig. 2). Memory performance was impaired in the single stimulation group compared to both sham and double groups only if we consider no mathematics inside memory measurements (Fig. 1) for both one-way ANOVA ($p\text{-value_PCS} = 0.0041$, $p\text{-value_PCLS} = 0.0137$) and two-way ANOVA ($p\text{-value_PCS} = 5.64e-07$, $p\text{-value_PCLS} = 2.8e-05$). A significant effect of tDCS was observed for memory performance without math in span sizes “four” and “six”. The time of recall showed a trend for a decrease in the single stimulation group in comparison to others (Fig. 2) according to one-way ANOVA ($p\text{-value_t_recall} = 0.0738$) and was significant for spans “five” and “six” in two-way ANOVA ($p\text{-value_t_recall} = 0.000986$). The difference between other measurements remains not significant.

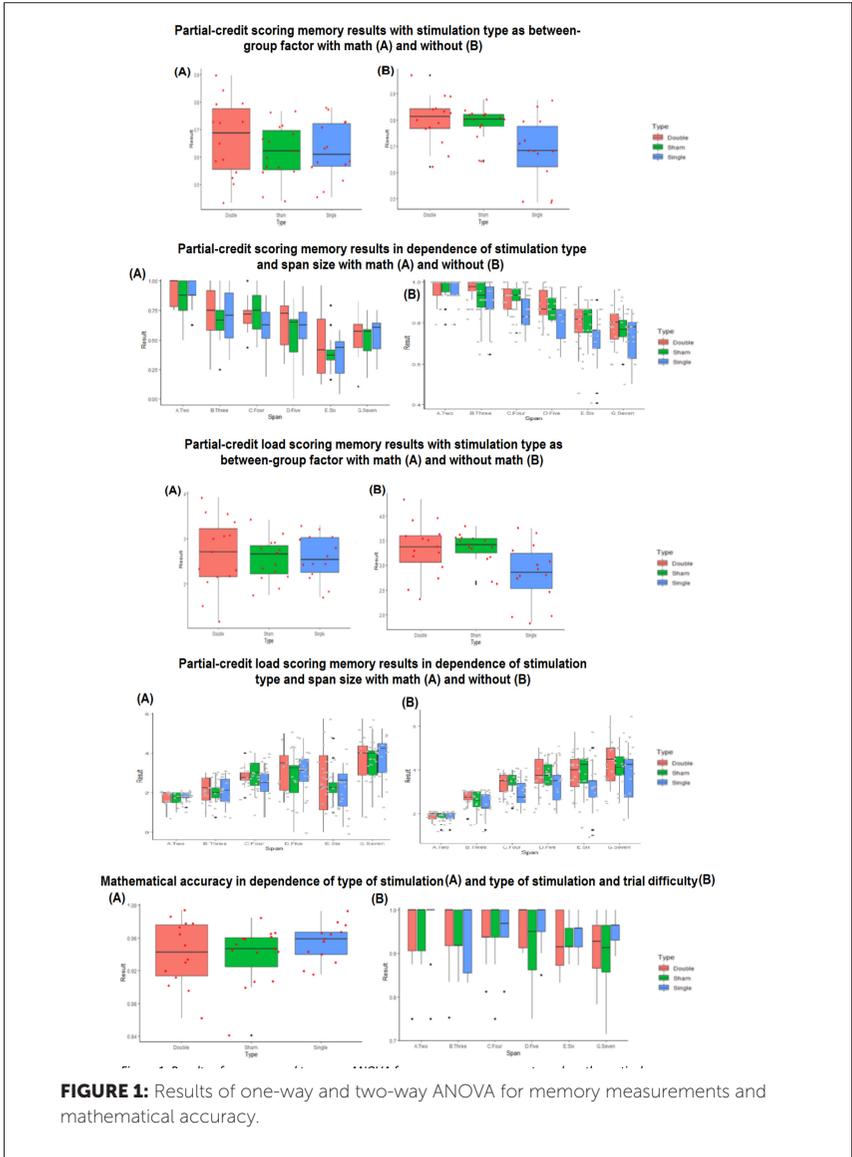

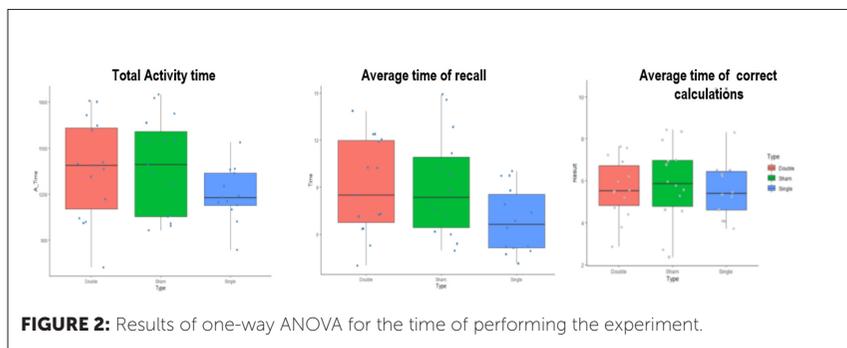

FIGURE 1: Results of one-way and two-way ANOVA for memory measurements and mathematical accuracy.

DISCUSSION

The results go beyond our initial hypothesis that stimulation will improve WMC. In the experiment, memory results without math were impaired only after a single stimulation, but not double. We assume that such effect was observed due to desynchronization of the components of the FPN, which was restored in case we apply the same stimulation protocol to the second component (P3). Thus, the results indicate that the frontoparietal network functions as not a single cognitive unit, but as two separate and highly interconnected neuronal units. By modulating the synchrony of the components of the FPN by tDCS, we were able to modulate working memory capacity during the operation span task. This explanation goes in line with several investigations, where the synchronization between brain areas, which are responsible for particular cognitive function, was important for task success (Hill, Rogasch, Fitzgerald & Hoy, 2018; Luria, 1966). We suggest that frontoparietal desynchronization manifests itself on a cognitive level by an attentional shift towards easier tasks (math) or impaired inhibition of irrelevant thoughts, which impair memory performance. Both explanations allow understanding the presence of tDCS effect to memory, but not mathematics.

INTRODUCTION/MOTIVATION

Over the last century, neuroscience has struggled to understand how synaptic organization contributes to the functional organization of the brain. Traditionally, most of the studies regarding the synaptology of human brain have been performed using conventional electron microscopy and stereological methods on single, two-dimensional tissue sections. However, these methods carry several major issues, since the identification and classification of synapses often represent a difficult task, which led to an erroneous characterization of the synaptic organization (1). Furthermore, previous electron microscope studies have reported differences in the synaptic organization in different cortical regions and layers (2–8). In the present study, we have focused on the synaptology of layer V of the human entorhinal cortex (EC), a crucial region located in the medial temporal lobe, essential for memory functions and spatial navigation (9). To this end, we have used Focused Ion Beam / Scanning Electron Microscopy (FIB/SEM). This methodology provides a large number of serial sections of the neuropil at an ultrastructural resolution, allowing 3D reconstruction of synapses, in which the synaptic organization could be accurately performed (10).

METHODS

Human brain tissue was obtained from autopsies from 2 males and 1 female subjects (supplied by Unidad Asociada Neuromax, Laboratorio de

Neuroanatomía Humana, Facultad de Medicina, Universidad de Castilla-La Mancha, Albacete, Spain), and processed for electron microscopy as detailed elsewhere (3,5). The 3D study of the samples was carried out using a dual-beam microscope (Crossbeam® 540 electron microscope, Carl Zeiss NTS GmbH, Oberkochen, Germany), which combines a high-resolution field-emission SEM column with a focused gallium ion beam (FIB). This allows the removal of thin layers of material from the sample surface on a nanometer scale. After removal, the exposed surface of the sample is imaged by the SEM. The sequential automated use of FIB milling and SEM imaging allowed us to obtain long series of photographs of a 3D sample on selected regions (10). A total of 9 stacks of FIB/SEM images of the EC layer V neuropil were obtained and analyzed using EspINA software (Figure 1) (11). Synapses were fully 3D reconstructed and classified as asymmetric (AS or type I) or symmetric (SS or type II), based on the thickness of the post-synaptic density (12,13). In addition,

geometrical features (size and shape) of the synapses were determined using EspINA software, which extracts the Synaptic Apposition Surface (SAS) and provides its morphological measurements (Figure 1) (14). Finally, postsynaptic elements of the synapses were also studied with EspINA software.

RESULTS AND DISCUSSION

The present study constitutes a detailed description of the synaptology of human EC layer V. Data are based on the study of a large number of synapses (1334), fully reconstructed in 3D at the ultrastructural level. In those synapses, we analyzed the following parameters:

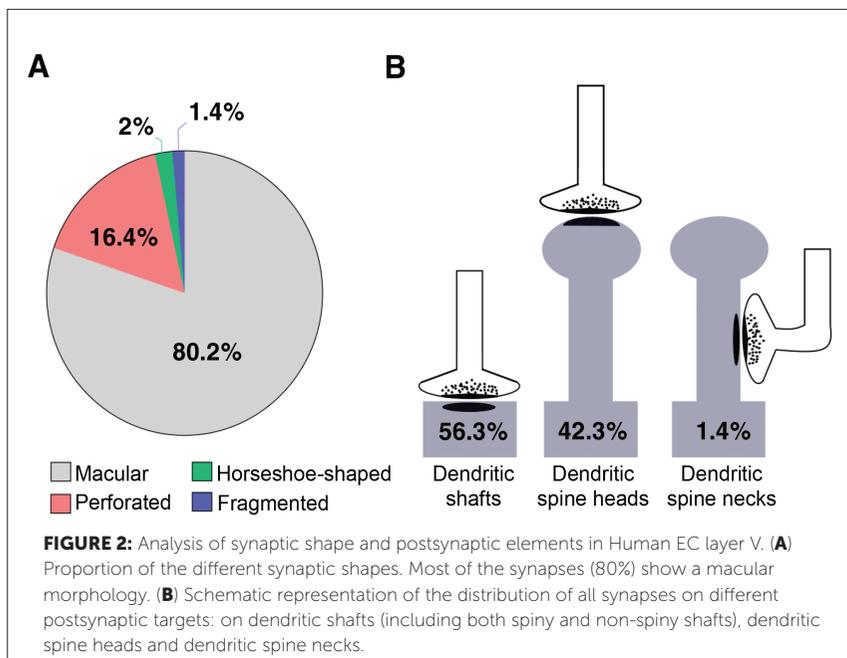

-Synaptic Density and Proportion of Excitatory and Inhibitory Synapses:

Synaptic density values were obtained by dividing the total number of synapses identified and included within a stereological counting frame (CF) by the total volume of the CF. The average synaptic density of the EC layer V was 0.39 synapses/ μm^3 and the proportion of AS:SS was 95:5.

-Synaptic Size: The study of the synaptic size was performed analyzing the area of the SAS of each synapse reconstructed. In layer V, the average of the SAS for the AS was 122 071 nm^2 , and 73 713 nm^2 in the case of SS. Thus, the SAS of AS were significantly larger than SS (Mann Whitney, <0.0001).

-Synaptic Shape: Synapses were classified into four categories: macular, perforated, horseshoe-shaped or fragmented (detailed in (7)). 80.2% of the synapses presented a macular morphology, followed by 16.4% perforated, 2% horseshoe-shaped and 1.4% fragmented (Figure 2). Since the vast majority of synapses presented a macular shape, we determined the proportions of AS and SS for that particular morphology, revealing that, of the total macular synapses, 96% were AS and 4% were SS.

-Postsynaptic Elements: Postsynaptic targets were identified and classified as spines and dendritic shafts. When the postsynaptic element was a spine, we distinguished the location of the synapse on the neck or on the head of this spine. When the postsynaptic element was identified as a dendritic shaft, it was classified as spiny or non-spiny, according to the presence or

not of spines (3). Most synapses were established on dendritic shafts (56.3%, 27.1% on spiny shafts and 29.2% on non-spiny shafts), followed by a 42.3% established on spine heads and a 1.4% on spine necks (Figure 2).

Further analyses are currently ongoing, which will both complete the synaptic study of layer V and include new layers, in order to provide a detailed description of the synaptology of the human EC. In any case, these results highlight the importance of the methodological approach presented here, which guarantees a precise characterization of the synaptic structure, avoiding most of the problems associated with traditional methods (1,10). The characterization of synaptic structure is crucial for a better understanding of synaptic function. For instance, differences in the excitatory/inhibitory balance are influenced by changes in the proportions of AS and SS synapses (15). Likewise, synaptic size and shape correlate with synaptic strength and

plasticity (16,17). Therefore, the use of this experimental approach is essential to fully understand the microcircuits that shape human brain and its functional organization, both in health and disease.

INTRODUCTION/MOTIVATION

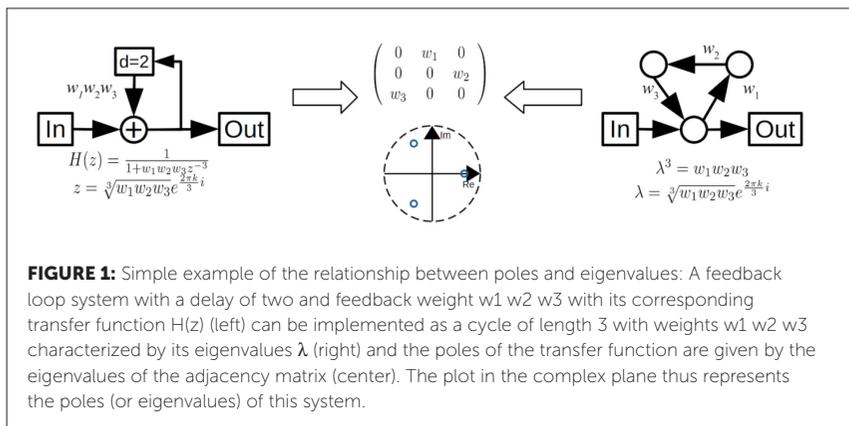

Artificial Recurrent Neural Networks (RNNs) are increasingly used in neuroscience research to explain neurobiological phenomena while considering the architectural and computational constraints of biological networks. Such an approach aims to train an RNN using machine learning tools and then compare it to the network dynamics observed in the brain [1]. Credit assignment in RNNs is classically performed using backpropagation-through-time (BPTT), the temporal analog of the standard backpropagation-of-error algorithm [2]. However, it remains unclear if BPTT learns solutions to dynamic problems similar to those employed by the brain, particularly because deep learning algorithms are often considered black boxes [3]. In this work, we aim to address this fundamental algorithmic question for learning dynamic time series by exploring the spectral structure of RNNs trained via BPTT on temporal tasks. Specifically, we take single-variable time-series processing tasks and compare the solutions found by BPTT against solutions based on feedback loops. Since feedback loops are widely used in control theory [4], are known to be efficient in time-series processing [5], and are also very prominent in neuroscience [8-11], particularly cortical circuits [12], they are ideal candidates for this comparison.

METHODS

Teacher forcing is a technique that is frequently used in dynamical supervised learning tasks where the model (student) receives the ground truth output $d(t)$ (teacher) as input in the subsequent computation of the behaviour of the network [13]. In a biological context, this learning paradigm corresponds to an agent that tries to imitate the responses of another agent by observing its

inputs and outputs. In our context, this framework allows us to design tasks that we understand perfectly, and since the teacher and student are both neural networks with the same activation function, we also know that the student is, in principle, capable of imitating the teacher flawlessly. We employ such a teacher-student model where a teacher network is generated and given Gaussian noise as input, and the student network is trained via the BPTT algorithm to apply the same function as the teacher. In our case, we consider linear systems that process input time-series through feedback loops.

In linear and linearizable networks, a system with feedback loops is fully characterized by its poles, which can be realized as the eigenvalues of the weight matrix of a linear neural network (see Fig. 1). As multiple weight matrices can implement the same dynamics by having identical eigenvalues, we compare teacher and student networks not by their network structure but by their eigenvalues representing their primary modes of activity. We find that BPTT rarely finds the same eigenvalues for the student network as the teacher, implying that the networks are fundamentally different despite implementing a similar function. Interestingly, only when network resources are increased, i.e., the number of neurons is much larger than the number of poles, can BPTT find the right solution. Additionally, the eigenvalues found by BPTT tend to be real even if the teacher has complex eigenvalues.

RESULTS AND DISCUSSION

Our first results illustrate that BPTT finds solutions that can obtain good performances in different temporal tasks, but it does so via network structures that do not always align with the feedback loop architecture (Fig. 2). This is especially true for tasks where the order of the underlying filter is high (see Fig. 2c), implying that BPTT might not be ideally suited to model temporally very complex systems as often observed in the real world. Thus, our results add to the evidence [14] that the brain does not use backpropagation-through-time for time-series learning. Moreover, since the identified analytical solutions are known to be efficient both in theory and in practice, and we also know that biology uses feedback loops for control [6-9], we should be careful when using BPTT to understand recurrent biological networks.

Lastly, our results also generalize the limitations of BPTT to other domains. For instance, to enable good learning performance, the size of an RNN needs to increase very fast with the order of the system to be imitated. This makes it generally difficult for small embedded applications and neural systems based on small RNNs. Furthermore, since the design of stable systems requires understanding the poles and eigenvalues of constituent systems [4], our work might help design RNNs for fields with critical failures to ensure the stability of performance guarantees. In future work, we plan to extend RNN training to more complex tasks, like forecasting chaotic time-series, and then

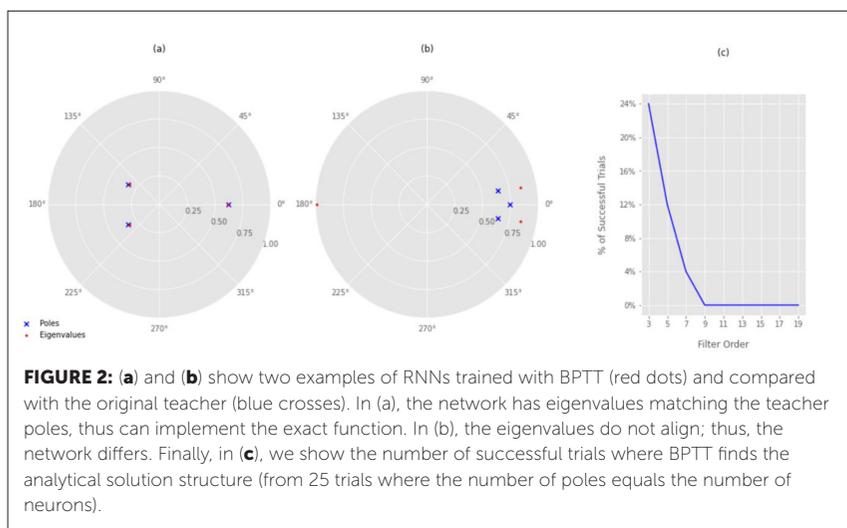

FIGURE 2: (a) and (b) show two examples of RNNs trained with BPTT (red dots) and compared with the original teacher (blue crosses). In (a), the network has eigenvalues matching the teacher poles, thus can implement the exact function. In (b), the eigenvalues do not align; thus, the network differs. Finally, in (c), we show the number of successful trials where BPTT finds the analytical solution structure (from 25 trials where the number of poles equals the number of neurons).

use our results to improve artificial RNNs by adding the required feedback structure, a known method to improve RNN performance [15] without BPTT.

INTRODUCTION/MOTIVATION

Between-subject brain variability in shape and function is a major challenge to the definition of accurate brain models [1, 2]. It also obscures the comparison between species. Recently, precision mapping has started to provide data to ground the definition of accurate brain models [3]. Yet technology has been missing to identify correspondences between brains. Leveraging Optimal Transport (OT) methods [5, 6], we derive an algorithm, denoted as Fused Unbalanced Gromov Wasserstein (FUGW), to compute whole-brain mappings between subjects with minimal anatomical priors, and provide a fast GPU-based Python implementation. We apply it to the Individual Brain Charting (IBC) dataset - a collection of more than 200 maps of functional activations (contrasts) acquired in each of the 12 human subjects [4]. We also provide a web-based tool to explore IBC as well as derived mappings. This is ongoing work and we intend to later on (a) run these methods on other MRI datasets, including resting state and naturalistic stimuli and (b) to assess the existence of cortical reorganisations between species, pushing forward recent efforts made in cross-species comparisons [8, 9, 10].

METHODS

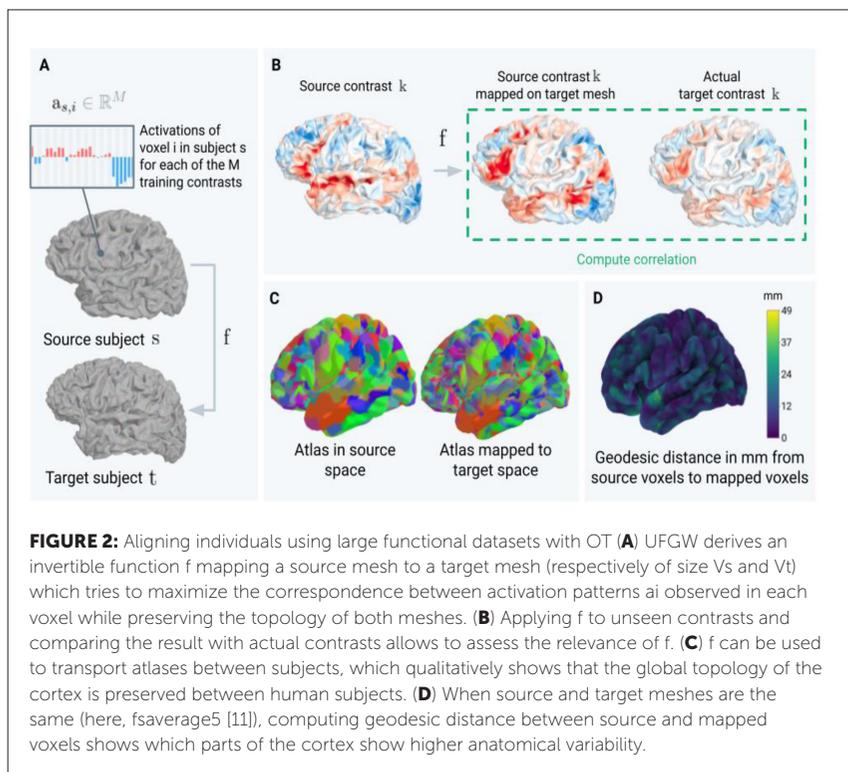

In short, a contrast map for a given subject represents the activity of each part of the cortex after the subject has been exposed to a specific stimulus (for instance seeing an image of a familiar human face, hearing a complex sentence, or hearing mathematical assertions). As illustrated in Figure 1, anatomies from one human subject to another vary greatly, as well as the activation maps elicited by similar stimulus. Alignment aims at alleviating these differences. Like other methods, FUGW focuses on building mappings for surface-sampled contrasts, which we obtain by projecting volume-based fMRI

data using Freesurfer [11]. We compare several methods to build mappings between cortical surfaces. We identify three main categories of methods:

1. topologically-loose methods such as point-wise nearest neighbours, which map source and target cortical areas based on functional information only (contrast map) without taking anatomical information into account
2. well known diffeomorphic methods such as Procrustes [12], Multimodal Surface Matching (MSM) [7] or spherical daemon [13], which align source and target subjects based on function information while enforcing derived mapping to be continuous between surfaces
3. FUGW, which we advocate is a combination of the two previous categories, as it doesn't enforce diffeomorphicity between source and target surfaces but only fosters it

In order to compare them, we systematically evaluate the relevance of derived mappings by (a) quantitatively assessing how well they transfer unseen contrasts and (b) qualitatively looking at the cortical reorganisation they induce between subjects through a dedicated web-based interactive visualisation tool. Our process is the same for all methods: one derives a mapping function for every pair of source and target subject of IBC using a set of training contrasts (see Figure 2.A). This function can then be used to map test contrasts

from the source anatomy to the target anatomy. Computing correlation between these mapped contrasts and the actual target contrast allows us to derive a metric to compare these methods (see Figure 2.B). Manually exploring derived mappings also helps assessing their anatomical relevance: one can map atlases from source to target (see Figure 2.C), measure distance on the cortex between mapped points in some specific case (see Figure 2.D), or explore them in our viewer.

RESULTS AND DISCUSSION

Topologically-loose methods correctly align primary areas of the cortex between subjects, but fail to correctly map areas involved in more complex tasks. Classical OT methods (simple Wasserstein distance) with no anatomical

priors yield similar results. These can be greatly improved by adding little topological constraints on the derived mappings (which is what FUGW does). Contrast maps transferred from source subjects to target subjects using these functions show high correlation with contrast maps acquired for these target subjects. On top of being computationally very efficient and easy to deploy, FUGW outperforms other alternatives. It makes it possible to capture subtle changes between individuals, such as the size and shape of functional areas or their position relative to other areas. Our visualisation tool facilitates exploring these changes. Moreover, as our method is not based on anatomical landmarks, it is particularly suited for cross-species comparisons (e.g. human vs. macaques).

INTRODUCTION/MOTIVATION

The past decade has seen a tremendous development of connectomics approaches [1], but most of them cannot bridge the gap between the micro-scale level of single-cell resolution and the meso-scale level of whole-brain bulk axonal projections. Electron microscopy [2] and direct synaptic labeling [3] cannot scale up to the whole brain level, while anatomical tract-tracing [4] and diffusion tensor imaging [5] cover the whole brain but lack single-cell resolution. One way to bridge the gap could be given by automated tissue-to-volume reconstructions of single-neurons based on fluorescence micro-optical sectioning tomography (fMOST) [6] or light-sheet fluorescence microscopy [7]. However, fully automated techniques are inadequate to precisely identify the brain areas, cortical layers and subcortical nuclei of the axonal tree terminals, when compared to manually traced neuronal reconstructions. The reason is that automated techniques do not allow experimenters to place a reconstructed neuron in a reference atlas, curate the position of each soma, dendrites or axonal terminals, and compare the final outcome with the original experimental tissue. Moreover, tens of thousands of neuronal reconstructions are needed to reach a whole-brain coverage similar to [4]. As a consequence, we have developed a tool for searching similar neurons across databases, based on their axonal morphology and registration coordinates, and correcting the cortical layer distribution patterns. As a use-case, we compare neurons from high-throughput databases with a small repository of manually traced and precisely placed neurons from a recently developed pipeline.

This pipeline labels single-neurons according to [10], followed by manual reconstruction using NeuroLucida [11] and registration to the volumetric space of the Allen Common Coordinate Framework v. 3.0 [12]. Finally, the neuron is shifted towards or away from the cortical surface to bring the manually annotated layer borders as close as possible to those of the atlas.

METHODS

We compared two sources of reconstructed neurons from the large online repositories of MouseLight [8], and Braintell [9] (labeled as high throughput neurons), with a smaller one produced by an in-house pipeline that is currently under development (labeled as 'reference' neurons). We first load each reference neuron as a 4D point cloud, with the first three dimensions representing the spatial coordinates and the fourth one representing the distance from the soma. We then use an API to download all high throughput neurons whose soma distance from the reference neuron is lower than a given threshold. We then apply the Coherent Point Drift (CPD) method [13] to compare all neuronal pairs through a two-step registration process. Initially, CPD finds the missing correspondences between the two neurons by minimizing the negative log-likelihood that the reference neuron's point cloud was sampled from the distribution of the high throughput one, as modelled by a Gaussian Mixture Model. Subsequently, CPD applies a rigid transformation of the high throughput point-cloud to the reference one (Fig. 1). We thus select the high

throughput neuron with the minimum negative log-likelihood as the neuronal match. Lastly, we load the SBA composer [14] tool to visually compare all selected pairs in 3D.

RESULTS AND DISCUSSION

Our approach represents a significant extension to existing tools, since the extent of the full axonal tree, instead of only regions of interest, is taken into account. Moreover, it is applicable to neurons reconstructed in smaller laboratories and allows for integration with other similarly registered datasets. The pipeline is expected to be updated before the end of the year with one-to-one matches of reconstructed neurons between our repository and the Mouselight and Braintell ones. In addition, we intend to compare the matches in terms of coverage in brain areas, cortical layers and subcortical nuclei. With the integration of neuronal reconstructions from multiple datasets, we will proceed to a number of future steps. We intend to translate the reconstructed axonal morphologies into a statistical model for the underlying axonal projections similarly to [15], characterize the overlap between axonal arbors and replicate the axonal trees to densely fill the volumetric space. Lastly, the tools, pipeline and models will become part of EBRAINS infrastructure.

IV Systems & cognitive neuroscience

Reality monitoring in native and foreign language

Aleksandra Dolgoarshinnaia*, Beatriz Martín-Luengo*

Centre for Cognition and Decision making, National Research University Higher School of Economics Institute for Cognitive Neuroscience, , Moscow, Russian Federation

INTRODUCTION/MOTIVATION

Reality monitoring (RM) is a type of source monitoring for which individuals have to distinguish between internally and externally generated memories [1]. Discrimination between external and internal sources of memory is suggested to rely on specific perceptual and cognitive characteristics that are intrinsic to these sources and serve as cues for memory monitoring [1] [3]. For instance, greater cognitive operations are typically linked to self- or internally-generated information, whereas greater sensory and contextual content is related to externally-generated information [1][3]. These different cues usually result in higher proportions of correct attributions to the self-generated information than for the externally-generated one [1][4][5]. In previous research we found that in bilinguals source monitoring processes might differ depending on the language in which information was presented [2]. Therefore, we designed a new cross-linguistic experiment to further test this, expecting that participants would remember better the words said or read aloud by themselves compared to the words pronounced by another person. As for incorrect attributions, there is a particular effect observed in the studies – externalization bias which suggests that participants more often misattribute the foil not presented items to the external source than to the internal one [3][4][5][6].

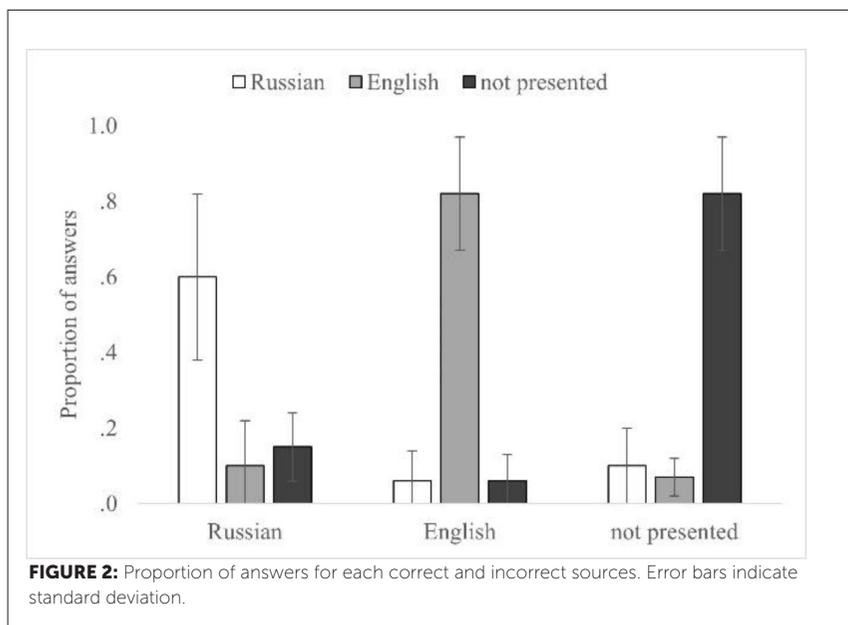

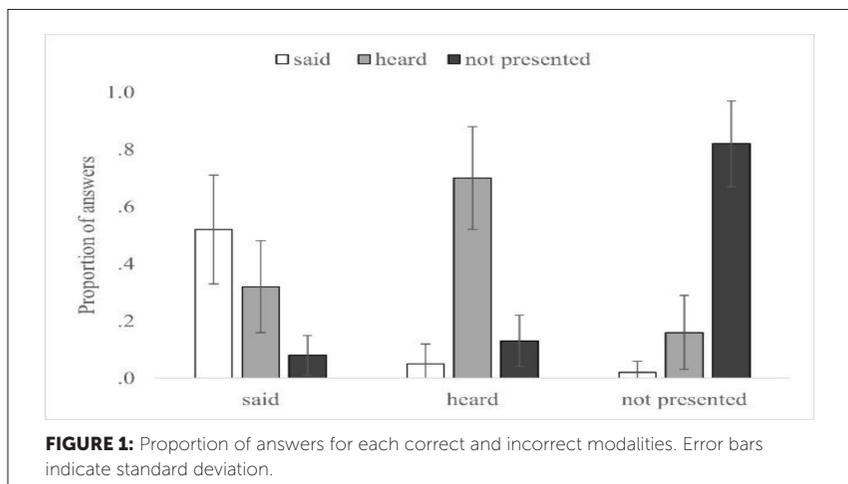

To date, RM was not specifically tested in a cross-linguistic experiment using self- or other-generated paradigm. Yet, results of studies implementing Deese–Roediger–McDermott paradigm suggest that in bilinguals false recognition is typically higher in the more proficient or dominant language [7]. Therefore, overall, we expected more incorrect answers to be found for the Russian language.

METHODS

Fifty-six Russian-native participants (38 females, mean age = 25.3 SD = 5.77) who scored minimum of 16 points (M = 20.8, SD = 3.1) on English proficiency test (<https://www.cambridgeenglish.org>) completed the online experiment ("Gorilla"[8]). We used a 2 (language: Russian, English) x 2 (modality: heard, said) within subject design. Our stimuli comprised 40 high frequency common nouns in Russian and English cross-translated resulting in 40 pairs of words as well as 20 pairs of foil not presented words. The language and modality of the presentation were fully counterbalanced. Participants either read aloud or listened to words presented on the screen either in Russian, or English. Then, they performed a recognition test, followed by reality monitoring (modality) and source monitoring (language) tasks.

RESULTS

Regarding general recognition, the 2x2 ANOVA with proportion of correct responses showed the main effect of the modality reflected in higher proportions for said modality (M = .82, SD = .23) over heard modality (M = .75, SD = .23), p = .02, as well the main effect of the language as the proportion of correct answers for English words (M = .87, SD = .23) was higher than for Russian words (M = .69, SD = .16), p < .001. The interaction between the language and modality, however, was borderline not significant, p = .055. Regarding analysis on reality monitoring, the said modality (M = .52, SD = .19) demonstrated the lowest rate of correct attributions among the three conditions, p < .001. Further analysis for incorrect modality attributions (see Figure 1) showed that in both, said and not presented conditions, misattributions to the heard modality (said-to-heard: M = .32, SD = .16; np-to-heard: M = .16, SD = .13) were significantly higher than to respective alternatives, p < .001. Finally, analysis on source monitoring (see Figure 2) showed that correct attributions to the English (M = .82, SD = .15) and not presented (M = .82, SD = .15) sources were higher than for the Russian source (M = .60, SD = .22), p < .001. Regarding incorrect source attributions, analysis for the Russian and not presented sources showed that incorrect attributions to the English source (Russian-to-English: M = .10, SD = .12; np-to-English: M = .07, SD = .58) were lower than for the not presented and Russian (Russian-to-np: M = .15, SD = .09; np-to-Russian: M = .10, SD = .10), respectively, p < 0.5. At the same time, for the English source analysis showed no significant difference in misattributions to the Russian or not presented sources, p = .723.

DISCUSSION

Firstly, the expected interaction between the language and the modality of the words was not found. Secondly, while previous studies on RM report overall better accuracy for self-generated information, our explicit test showed that correct attributions to the said modality were the lowest. One explanation to such results can be the presence of the externalization bias as reflected by higher proportion of misattributions of not only not presented items to the external source, but of the internally generated items as well. Overall, this suggests that words said by the participants possessed enough cues or “weight” to be recognized as presented on the recognition test, however, not enough to indicate whether the word was self- or other generated. Finally, results on source monitoring suggest that processing information in English required more cognitive effort and therefore contained more characteristics related to internal cognitive processes that usually allow for successful monitoring.

To our knowledge, this is the first bilingual RM paradigm that manipulated not only the language of presented information, but the modality of its presentation. Although no direct interaction between the modality and the language was detected, there might still be differences in information processing and memory functioning when information is presented in the second language versus is the first language. To conclude, these results, specifically results on source monitoring, support the idea that monitoring information in the second language can differ from monitoring information in the first language. Nevertheless, further examination of these differences as well as the mechanisms of different types of monitoring processes is required.

INTRODUCTION/MOTIVATION

Multiple evidences prove how brain oscillations at different frequencies underlie several processes of key relevance for human behavior, such as, long-distance brain coordination, cognitive and perceptual processes, or plasticity and brain maintenance through life [3][4][6][10]. Nowadays, numerous studies power estimates of the different bands of the frequency spectrum as potential biomarkers for different pathologies. However, little is known about the typical diachronic development of these markers during development and aging in life, which should be an important pre-requisite for its use under pathological conditions. Classically, power changes throughout life have been described using simplistic models based on linear fittings; due to restricted sample sizes or limitations in methodological approach. This classical conceptualization assumes, therefore, a monotonic and constant change that may not adjust to the developmental complexity. Moreover, previous literature is not consistent regarding these changes' direction; reporting both increases and decreases for specific frequency bands depending on the study [1][2][7][8][12][13]. A complementary topic when studying ongoing oscillatory brain activity

is the study of natural frequencies distribution through the cortex. Different brain regions show a *natural tendency* to synchronize its neuronal activity at different frequencies, the so-called “natural frequencies”. However, there are also few studies regarding topographic distribution of natural frequencies and its evolution during development and aging. The motivation of this study was to properly describe how brain activity changes due to the healthy maturational process. For that reason, our main objective was to characterize in detail, the profile of electrophysiological evolution in healthy development and particularly, unveil whether brain activity changes during aging could be related with cognitive performance to assess whether these changes can be interpreted as a scaffolding compensatory mechanism or rather as a sign of brain tissue and activity deterioration during normal aging.

METHODS

For this study, brain activity of 792 healthy participants (13-80y/o) have been characterized using Magnetoencephalography.

Firstly, signal was filtered (using temporal-Signal-Space-Separation), then artefacts were removed, and Independent-Component-Analysis was applied (to discard Electrooculogram and Electrocardiogram components). After signal was pre-processed, the activity of each subject in each of the 1202 cortical sources was reconstructed and their relative power was calculated using Beamformer Linearly-Constrained-Minimum-Variance.

Regression models-power and age: Power in each frequency band and age adjustment was evaluated considering three possible fitting models (linear, quadratic, and cubic) by using multiple regression analysis, and Likelihood-ratio-test to evaluate the best model (corrected p-values by FDR, $q = 0.05$).

Natural frequencies: The natural sources that generate each brain rhythm, as well as its modification through the life continuum were studied by conducting Pearson’s correlations between relative source contribution (z-value; standardized value of each source’s power value compared to the other sources in each band) and age (ρ). Rho values obtained represent how sources change its relative contribution throughout maturation.

Cognition: Performance in different cognitive test domains were studied; to reduce dimensionality Principal Component Analysis (PCA) was conducted; so finally, we had five main cognitive domains: Declarative Memory, Working Memory; Processing Speed; Visuospatial Memory and Verbal Fluency. To analyse the potential relation between cognitive domain scores and power in each band, partial correlations were applied between performance in each cognitive domain and power in each source and band (corrected by age due to its relevant role in cognitive performance and power trajectory), estimating the potential correlation (ρ -values) between each band power and cognitive performance in each domain.

RESULTS AND DISCUSSION

Results showed a specific topographic distribution of the generators for each band, which was modified through life. Likewise, power change patterns were observed in each band through life following different statistical adjustments depending on the frequency band and cortical region analysed (Fig1).

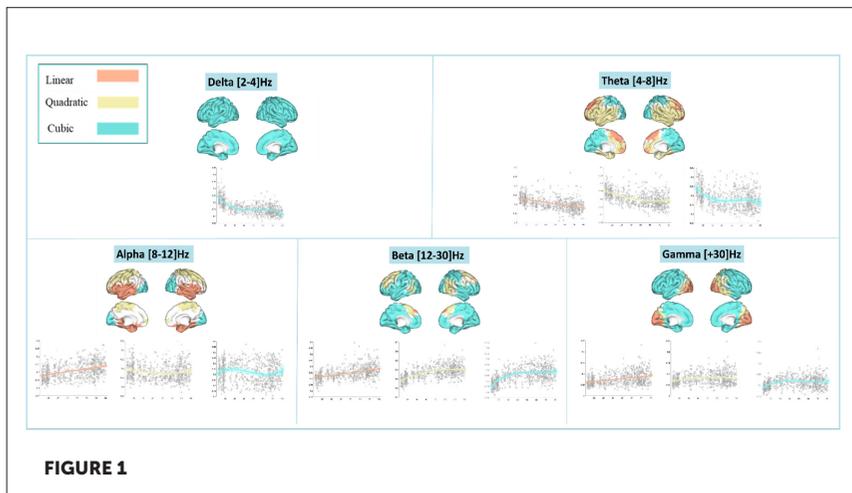

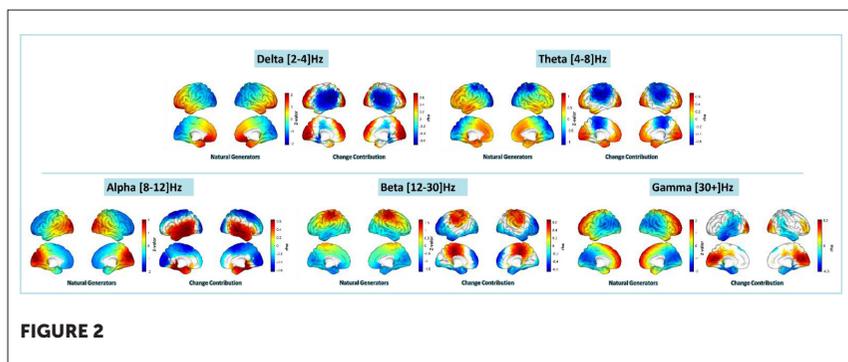

FIGURE 1

Although there were regions in which a linear model could give a better explanation of the changes across the life continuum, mainly, complex adjustments gave a significantly better explanation of the diachronic changes. In addition, natural generators, despite being relatively stable, modify their topography on the cortical surface through life (Fig2).

The main conclusions of this research were: Firstly, there was a relation between age and the different cerebral rhythms, and this relation is not strictly linear. Also, that evolution depends on the topographical region as well as the band. It was also interesting the fact that the more pronounced changes in electrophysiology for all classical bands were found during the first decades of life (13-30y/o) matching with youth maturation [14] and in the last ones [11] (60-80 y/o), the typical age range associated with the aging process. Interestingly, most fitting models showed a steady plateau during middle age, in which rhythms tended to be more stable. Secondly, regarding natural frequencies distribution, there were topographical changes for each band (Fig2). For slow waves (< 8Hz) their main generators increase their importance with age; alpha's main generator, located in the occipital lobe, decreased its relevance in the life continuum increasing towards more anterior-temporal regions, and for gamma, its main generator also decreased its importance during life [5][9]. Regarding the relationship between power-cognitive performance during aging, we found a negative relation between beta power in occipital areas, and gamma in sensorimotor areas and working memory performance. For processing speed performance, there was a positive relationship between slow waves power, in somatosensory and sensorimotor areas, and a positive relation in beta in occipital lobe. Similar tendency was observed for visual memory, also showing a negative relation between slow

waves (delta in somatosensorial, and theta in occipital areas) and a positive relation for beta in occipital areas regarding the performance in this specific domain. No statistically significant correlations were found for the other cognitive domains. Remarkably, when closely interpreting the relationship observed between power in the aging portion of our sample and cognition, we observed that a more intense slow wave activity (i.e. delta and theta) and a less pronounced fast wave activity (beta and gamma) were associated to overall cognitive performance. This supports the notion that the changes we described in the resting-state power spectrum during normal aging represent a sign of brain activity deterioration rather than a compensatory attempt as they are accompanied by cognitive decline in all cognitive domains.

INTRODUCTION/MOTIVATION

So far, neurocognitive studies with trans individuals (i.e. people whose gender identity differs from their sex assigned at birth) have primarily focused on the question of whether their cognitive functions were more akin to their gender identity or their sex assigned at birth (see [1] for an overview). While this research did have its merits, it is barely of any relevance to trans individuals themselves [1]. The current project aims to leave this older path and instead puts trans individuals and trans issues in the focus of attention. Emotional and social processing is often considered a dividing factor between (cis) men and (cis) women, hence multiple studies used tasks relating to these processes to assess the masculinization/femininization of trans individual's brains [2][3]. Contrary to their intended outset, these studies found no differences between their cis gender groups, however they did detect a difference between their trans groups compared to both cis gender groups prior to the start of gender-affirming hormone therapy (GAHT). A difference that was no longer detectable after a few months of GAHT [2][3]. Interestingly, hormone levels alone were not enough to explain these changes [2][4]. These results make it evident that emotional processing changes over the transitioning process, but why or how this occurs has not yet been researched. This project consequently aims to start filling this gap by assessing emotional prosody processing (EPP) in trans women at multiple time points in their first year of transitioning, as well as by assessing long-term changes in EPP in trans women who have been using GAHT for over 2 years and correlating these findings with outcomes on a variety of psychological factors.

METHODS

The project consists of two experiments:

1. A longitudinal study consisting of trans women at the beginning of the transitioning process. They participate in the experiment at three different time points: T1 (before the start of GAHT and voice therapy), T2 (after 6 months of GAHT, which coincides with the end of voice therapy) and T3 (after 12 months of GAHT). The aim of this study is to evaluate changes in EPP over the course of the first year of transitioning.
2. A cross-sectional study, consisting of trans women after at least 24 months of GAHT and a control group of cis gender women and men, who lack a transitioning experience. This study aims to evaluate potential long-term influences of GAHT on emotional processing. The decision to include cis men in the control group has been made because cis women are more likely than cis men to take hormones for non-transitioning purposes, e.g. as contraceptive measures, which might influence findings.

Both studies use the same experimental setting. EPP is measured using two non-invasive instruments simultaneously: electroencephalography (EEG), which assesses the temporal component and functional near-infrared spectroscopy (fNIRS) which assesses the spatial component of EPP in the cortex. The experimental stimuli consist of a total of 180 pseudo sentences spoken in three different emotional valences (positive, neutral, negative) by two speakers (female and male sounding voice). For a more holistic approach, additional factors are assessed via questionnaires: physical and mental well-being, quality of life, body image, sense of belonging and autism spectrum traits.

RESULTS AND DISCUSSION

The project is still in an early stage, however, preliminary data from the control group has already been collected and a detailed statistical analysis will be available at the time of the conference. To our knowledge, this study will be the first to assess changes in EPP during the transitioning process. Based on studies on neural correlates of reductions in emotional processing capacity in various other groups, such as people with major depression (e.g. [5][6][7][8][9]), autism spectrum condition (for a meta-analysis see: [10]), parkinson's disease (e.g. [12][13][14]) or schizophrenia (for meta-analyses see: [15] and [16]), we propose the following hypothesis: We expect to see changes in the P200 and LPP (late positive potential) components of the EEG [17] and in the activation in areas relating to the STS/G (Superior temporal sulcus / gyrus) and

the IFG (inferior frontal gyrus) in the fNIRS [17][18]. These changes will point toward an increased capacity for emotional prosody processing. Furthermore, we expect more favourable outcomes on the questionnaires to correlate to more efficient EPP. In detail, for study 1, we expect the amplitude of the P200 in relation to emotional stimuli to decrease over the course of one year, indicating a more efficient emotional salience detection. Similarly, we expect the LPP to increase and to differentiate better between the different emotional valences with a maximum for positive valence over the course of one year. We also expect increased activation in the areas of the STS/G and the IFG. To our knowledge, so far no studies have attempted to capture long-term effects of transitioning on emotional processing, so potential outcomes for study 2 are harder to define. However, we expect similar results when comparing trans women to cis gender individuals, indicating a lasting effect of the transitioning process on EPP.

ACKNOWLEDGEMENT

I would like to thank my supervisor, Sonja Rossi, for her time and expertise, and for giving me the opportunity to work on a project I am truly passionate about. I would also like to thank Katharina Feil and Barbara Moser for their insights into transgender care and for their recruitment work. Furthermore, I would like to thank the University of Innsbruck, Vizerektorat für Forschung for the financial support of the project via a Doktoratsstipendium aus der Nachwuchsförderung der Universität Innsbruck, as well as the Department for Hearing, Speech, and Voice Disorders of the Medical University of Innsbruck for providing the equipment and room needed for the realization of the project.

Prospective metamemory monitoring: Source vs item

Elizaveta Ivanova*, Beatriz Martín-Luengo

Centre for Cognition & Decision Making, Institute for Cognitive Neuroscience, National Research University – Higher School of Economics, Moscow, Russia

**elizaveta.ivanova.w@gmail.com*

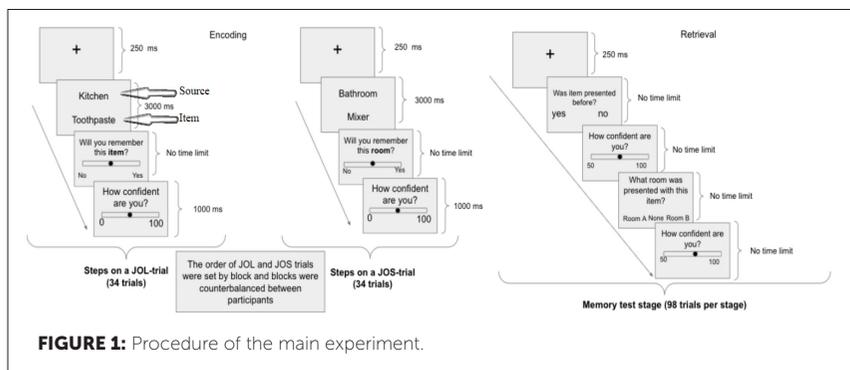

INTRODUCTION/MOTIVATION

Prospective metamemory is a subfield of metacognition, which refers to an individual's ability to predict and regulate one's own memory during encoding [1,2]. A real-life example of prospective metamemory can look like students assessing if the material they are learning at the moment is easy to remember when the test comes. Prospective metamemory can be studied from the perspective of how we make judgements regarding the source of the information (metamemory source monitoring) and judgements regarding the information itself (metamemory item monitoring). It is not clear yet whether source and item metamemory monitoring share similar mechanisms or not. On the one hand, early studies agree on the item- and source-monitoring similarity: whether item-source pairs were varied by emotional intensity or modality (source seen or imagined), participants' judgement about sources was positively correlated with their judgement about items [3-5]. On the other hand, a new study of Schaper et al. [6] showed that recognition rates were higher for incongruent pairs source-wise, and for congruent pairs item-wise. However, unlike early studies, Schaper et al. [6] used a between-subject design, which could potentially distort data analysis – due to lack of control of individual sensitivity toward metamemory judgements. Therefore, the main aim of this study was to disentangle whether source and item metamemory monitoring rely on the same monitoring mechanisms. To do so, we used 2 tasks: Judgement of Learning (JOL) to assess confidence in future remembering of an item and Judgement of Source (JOS) – a twin task of JOL for source metamemory monitoring [3,7]. To control for subjectivity, we used congruence between source-item as a varying factor, and to control for individual sensitivity, we chose a within subject design. We set three hypotheses: JOL and JOS will have a high similarity; congruent source-item pairs will have higher confidence ratings than incongruent pairs; and lastly,

recognition accuracy, despite differences in confidence ratings, will be similar for congruent and incongruent source-item pairs.

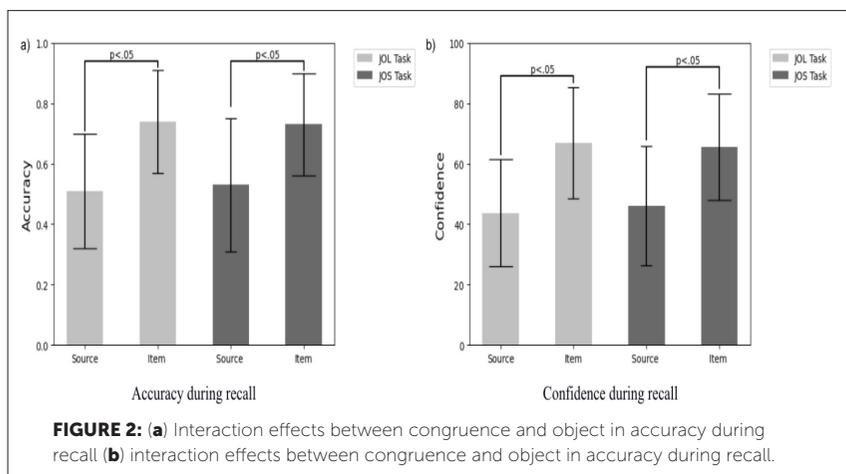

METHODS

First, we conducted an online normative study to select the stimuli for the main experiment. Final lists had 36 Source A-only-related items, 36 Source B-only-related items and 34 filler items related to both sources. For the main experiment, forty participants completed an encoding, a distractor task, and a memory test phases. The encoding phase contained two blocks: block-JOS (in which participants assessed their confidence about memorizing the source) and block-JOL (in which participants assessed their confidence about memorizing the item) (see Figure 1). Each block contained 36 items: 18 items were presented with a congruent source and 18 items with an incongruent source. Participants made either JOL or JOS (depending on the block) and rated their confidence of future remembering from 0 to 100%. Between JOL and JOS stages, participants had a short distractor task to unload short-term memory. During memory test, all items from the encoding phase including a similar amount of filler items were presented. Participants' task was to indicate whether a presented item was before and rate their confidence from 0 to 100%. If participants said the item was presented before, they were asked to name the source with which that item was shown and rate their confidence from 50 to 100%. The experiment was conducted online and build via Gorilla software [8].

RESULTS

The analysis of confidence during encoding showed an interaction effect of Congruence and Object (Item vs Source) ($p = .009$). Student *t*-tests showed differences in Congruent Source vs Incongruent Source ($p < .001$), Congruent Source to Congruent Item ($p < .001$), Congruent Item to Incongruent Item ($p < .001$), Incongruent Item to Congruent Source ($p < .001$), but not in Incongruent Source to Incongruent Item ($p = .59$). Next, we tested confidence and accuracy during memory test (Figure 2). For confidence, we found a significant main effect of Congruence ($p = .018$) and Object ($p < .001$). Analysis also showed a tendency towards significant interaction between Object and Task ($p = .022$). These main effects were qualified by their interaction: we found significant differences in every condition comparison except Item in JOS task vs Item in JOL task ($p = .72$). For accuracy rates, we found a significant main effect of Congruency ($p = .038$) and Object ($p < .001$). Analysis also showed a tendency towards significant interaction between Object and Task ($p = .058$). The post-hoc tests confirmed significant differences in every condition comparison except Item in JOS task vs Item in JOL task.

DISCUSSION

In this study we examined whether source and item metamemory monitoring are similar to one another and whether they are influenced by congruence. We found that JOL and JOS did not differ across measures of accuracy and pre- and post- learning confidence, that is, our participants had similar accuracy and confidence levels when focused on either source or item. The results are in line with previous studies that found strong positive correlation between JOL and JOS [3-5]. They also contradict previous results of Schaper et al. [6] study, which showed a stronger influence of congruence on JOS. In our analysis, congruence was shown to significantly influence both source and item, that is, the results of our participants were formed mostly by congruence factor. Taking together both results in JOL vs JOS comparison and congruence influence, we can suggest that mechanisms of source and item metamemory monitoring are similar. Moreover, we can conclude that item-source congruence positively influences both confidence and accuracy and is more important than choosing to focus on source or item. In future, the neural underpinnings of prospective metamemory monitoring (both source and item) can be explored.

INTRODUCTION/MOTIVATION

Alcohol dependency (AD) is characterised by disrupted reward processing, underpinned by dysfunctional cortico-striatal reward pathways.¹ Functional magnetic resonance imaging (fMRI) studies with AD subjects have generally shown reward processing brain regions are hypoactive (i.e., blunted) during reward anticipation²⁻⁴, and hyperactive during reward outcome.^{1,5} However, little is known about the biology reward processing in populations at-risk of AD, which could facilitate more targeted prevention and intervention strategies.

METHODS

Here, we used an electroencephalography (EEG) version of the monetary incentive delay task⁶ (Fig. 1b) to examine if young adults with hazardous alcohol use have disrupted reward anticipation (e.g., hyper/hypoactive relative to controls). This task involved responding to a target stimulus following reward incentive cues to win, or avoid losing, the cued outcome while brain activity was recorded under 64-channel EEG. Participants were recruited via university campuses and the Alcohol Use Disorders Identification Test (AUDIT) (i.e., alcohol harm screening tool developed by the World Health Organisation) was used to split participants into high audit (HA) (i.e., hazardous at-risk drinkers) (n = 22, mean AUDIT score: 13.82) and low audit (LA) (i.e., low risk for AD) (n = 22, mean AUDIT score: 5.77) groups. Trial averaged event related potential (ERP) and single trial machine learning (ML) discriminant analyses

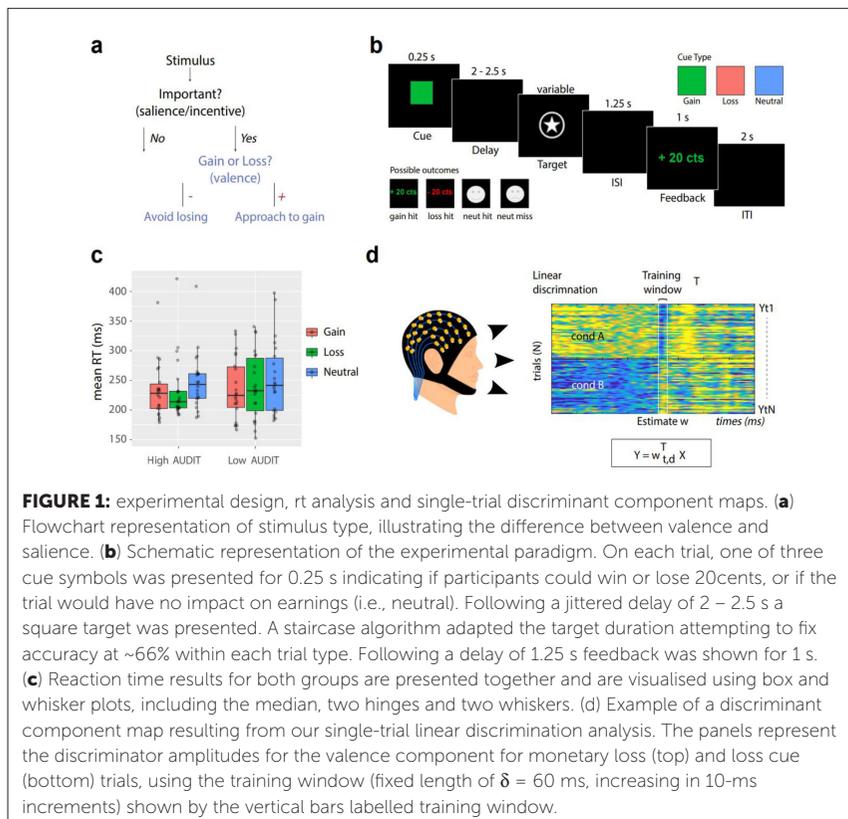

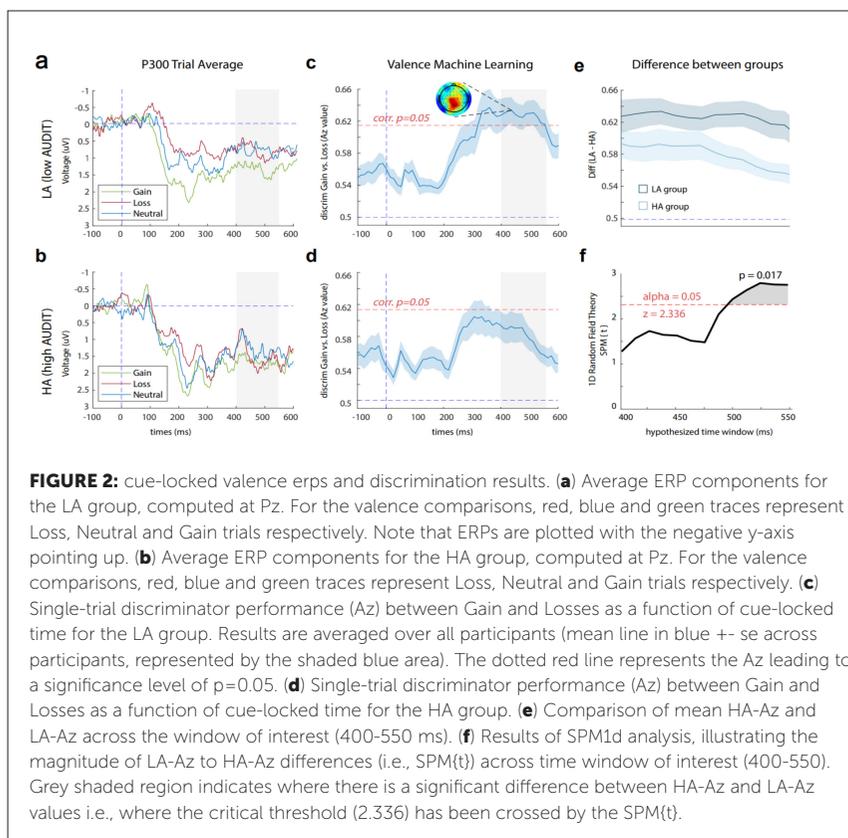

FIGURE 1: experimental design, rt analysis and single-trial discriminant component maps. **(a)** Flowchart representation of stimulus type, illustrating the difference between valence and salience. **(b)** Schematic representation of the experimental paradigm. On each trial, one of three cue symbols was presented for 0.25 s indicating if participants could win or lose 20cents, or if the trial would have no impact on earnings (i.e., neutral). Following a jittered delay of 2 – 2.5 s a square target was presented. A staircase algorithm adapted the target duration attempting to fix accuracy at ~66% within each trial type. Following a delay of 1.25 s feedback was shown for 1 s. **(c)** Reaction time results for both groups are presented together and are visualised using box and whisker plots, including the median, two hinges and two whiskers. **(d)** Example of a discriminant component map resulting from our single-trial linear discrimination analysis. The panels represent the discriminator amplitudes for the valence component for monetary loss (top) and loss cue (bottom) trials, using the training window (fixed length of $\delta = 60$ ms, increasing in 10-ms increments) shown by the vertical bars labelled training window.

was applied to the EEG data⁷ (Fig. 1d). ML discriminator performance was quantified by calculating the area under a receiver operating characteristic (ROC) curve (termed Az value) using a leave-one-out trial (LOO) cross validation approach. Az significance was assessed using the LOO procedure after randomizing the labels associated with each trial. Group averaged Az values were compared using one-dimensional Statistical Parametric Mapping (SPM1d), a method which corrects for multiple comparisons using random field theory to account for covariance between timepoints.⁸

RESULTS AND DISCUSSION

For the LA group, we observed a wide temporal window of significant valence discrimination (i.e., gain vs loss trials, Fig. 1a) during reward anticipation, with Az values exceeding the threshold $p < 0.05$ between 333 and 512 ms after cue onset (Fig. 2c). In contrast, the HA group was insensitive to valence at all time points between cue and target onset (Fig 2d). Az values were significantly larger in the LA group compared to the HA group from 480 – 550 ms (SPM1d $p_{cluster} = 0.017$) (Fig. 2e-f). Notably, the LA group but not the HA group, demonstrated a significant negative relationship between single-trial variability in valence component and reaction times for gain and loss trials

(estimated regression coefficients were significantly different than zero $t(21) = -2.14$, $p = 0.044$). There were no significant between-group differences in reaction time (Fig. 1c), ERP cue-P3 values (Fig. 2a-b) or salience discrimination (i.e., incentive vs neutral trials, Fig. 1a).

Young adults with at-risk drinking exhibited disrupted hypoactive valence processing, compared to those with low-risk drinking. Absence of EEG valence sensitivity in the at-risk group may reflect pre-existing blunted motivational mechanisms for non-drug rewards. Our single trial ML approach preserved variance among trials, thus improving signal to noise ratio compared with conventional ERP analyses. The single trial method allowed us to investigate the changing cognitive states of individual participants across the task and the relationship between their brain and behaviour. These benefits have clinical relevance as they could support patient diagnosis and stratification, where subtle individual differences in neural processing may be informative of predisposing vulnerability to addiction and potential treatment response.

INTRODUCTION/MOTIVATION

Perceptual learning (PL) refers to lasting improved perception skills after participating in targeted single or repeated training sessions. It has been shown that repetition of a certain cognitive task that involves PL can improve implicit memory and attention processes (Maniglia & Seitz, 2018). The application of PL can be categorized as fast when leading to improvements after a few sessions only (Leclercq, et al., 2014; Poggio et al., 1992) or slow when involving several training sessions (Seitz et al., 2005). Several EEG-ERPs studies on visual PL were able to shed light on the neural mechanisms underlying visual perception, for both fast and slow learning conditions (Mishra, et al., 2015; Song et al., 2008). However, no studies on fast PL distinguished between different visual stimulus categories (objects, animals, etc.). For instance, the study of Shahin et al. (2005) reported an enhancement of the P2 ERP component in response to musical sounds as a function of training and likewise in response to complex auditory patterns comprising sequences of individual frequencies (Atienza et al., 2002). Furthermore, Ji et al. (1998) showed a larger posterior N1 component for images of animals compared to images of vegetables and fruit. In particular, the N1 amplitude reflects visual discrimination processes, and its latency was affected by processing effort by showing a lower amplitude and larger latency for stimuli that are more difficult to discriminate. Although learning effects on ERPs components have been already studied, especially N1 and P2, the cognitive processes behind learning gains are still unclear. Previous ERP studies suggested that these changes might depend on several factors, such as improvements in processing of perceptual features (Hamamé, et al., 2011), access to perceptual representations (Sagi,

2011), and inhibition of irrelevant stimuli (Sheehan et al., 2005). One issue with these studies is the lack of information about how fast PL depends on stimulus category and what are the changes in ERP components when different stimuli are used.

METHODS

To address this, we recruited 16 participants and were administered a single session of a visual working memory task, called N-Back, that included three different stimulus categories. Our goal was to investigate the relationship between stimulus category (objects, animals, and fruit), and the P1, N1, P2, N2, P3 and N4 ERP components, and to better understand to what extent stimulus category impacts on learning-associated cognitive processes.

RESULTS AND DISCUSSION

Our results revealed that stimulus category affects both behavioural (Figure 1) and neurophysiological responses, and that fast PL is paralleled by changes in amplitude and latency of several ERP components: P1, N1, P2, N2, P3 and N4

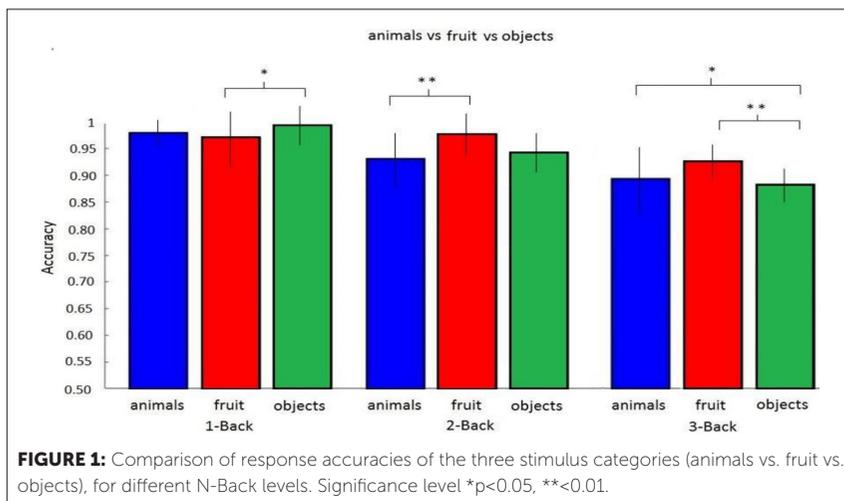

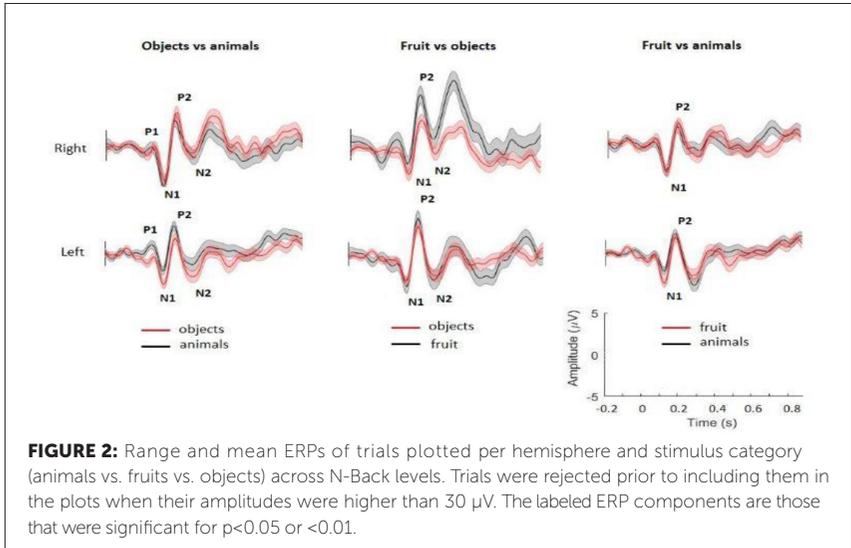

FIGURE 1: Comparison of response accuracies of the three stimulus categories (animals vs. fruit vs. objects), for different N-Back levels. Significance level * $p < 0.05$, ** $p < 0.01$.

(Figure 2). In addition to the well-established N1 and P2 amplitude changes, our observations provide evidence of the impact of stimulus category on fast PL in terms of amplitudes and latencies of other ERP components. In line with the study of Proverbio et al. (2008), we did not observe any significant correlation between ERP components and behavioural responses. In conclusion, our outcomes highlight that both behavioural and neurophysiological responses, in particular ERP components, reflect the impact of fast PL even when performing a single N-Back training session. Differing from existing literature, we considered several visual stimulus categories (objects, animals, etc.) and showed significant latency variations in different ERP components. Finally, the variety in used training lengths and stimulus repetitions (e.g., Song et al., 2008; Mishra, et al., 2015) led to changes in different ERP components, which we hypothesize to reflect fast or slow PL effects.

INTRODUCTION/MOTIVATION

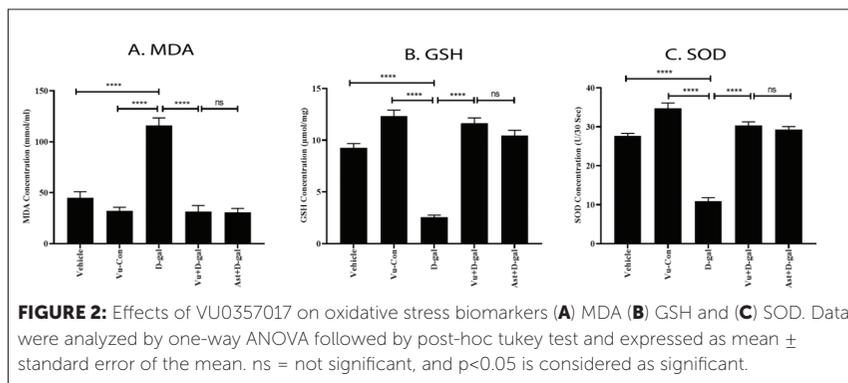

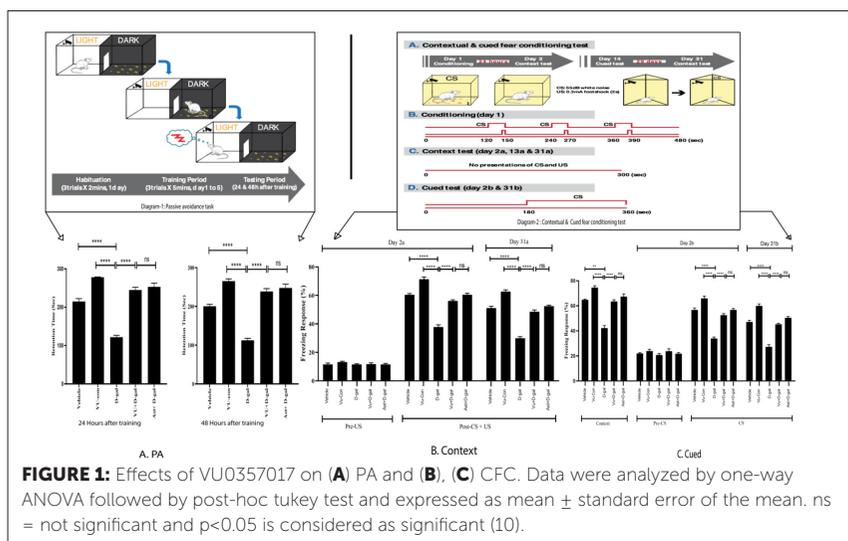

Aging-induced memory impairment results in loss of muscarinic receptors (mAChRs) (1). This causes massive oxidative damage by generating uncontrolled oxidative biomarkers (MDA, GSH and SOD) in the brain, commonly found in Alzheimer's disease (AD) (2). Studies have shown that mAChRs play a vital role in different learning, like spatial learning, contextual fear conditioning, and trace eyeblink conditioning, and serial feature positive discrimination tasks (3). Other studies showed that among the five subtypes of mAChRs, the M1 receptors are closely associated with learning (4). Several behavioral studies showed that the m1mAChR plays a vital role in attention and is a promising target for memory functions (4). Another study showed that m1mAChR controlled oxidative stress in the brain (5). Therefore, the m1mAChRs could be a promising target to improve memory in aging-induced AD (6). VU0357017 is a highly selective and potent m1 allosteric agonist having a substantial effect on hippocampal-dependent learning in rodents (7). Several studies showed that VU0357017 exhibits antioxidant properties by stimulating b-Arrestin pathway (7,8). However, no studies have investigated the beneficiary role of VU0357017 in aging-induced memory impairment and their associated biomarkers. Our study aims to find an effective treatment approach for AD using selective m1mAChR agonist VU0357017 by (i) establishing its cholinergic activity in mice via two commonly used behavioral tasks and (ii) identifying its regulatory activity in AD-associated oxidative stress biomarkers via a bioassay technique.

METHODS

A. Passive Avoidance (PA): On the first day, mice were free to roam in the testing chamber, considered habituation. Then they were subjected to a

mild foot shock (US) every day for seven days. Days 8-11 were devoted to the examination (testing period) (9). We computed the latency needed to pass through the gate that separates the two compartments (Diagram 1) (10).

B. Contextual Fear Conditioning (CFC): CFC includes keeping the animal in a novel environment, delivering an unconditioned stimulus (US: from the shocking device) associated with a conditioned stimulus (tone: CS), and then getting rid of it (day 1: conditioning session). When the animal was kept in

the same environment again, it showed a freezing response if it could recall (day 2a & 31a: context) (11). The responses were analyzed by changing the shape of the chamber (day 2b & 31b: cued session) (Diagram 2).

C. Bioassay: Oxidative biomarkers (MDA, GSH, and SOD) were measured from the hippocampus.

D. Animals: We divided forty mice into the following five groups: Group 1: Saline 1ml (n=8) (Intrapertontial; i.p) Group 2: D-gal (n=8): D-gal 100 mg/kg (12) (i.p) Group 3: VU0357017 (VU) (positive control; n=8): VU 0.15mg/kg (i.p) (13) (i.p) Group 4: VU0357017 (VU) + D-gal (n=8): VU 0.15 mg/kg (13) (i.p) and D-gal 100 mg/kg (12) (i.p) Group 5: Astaxanthin (Ast) (Standard Antioxidant) + D-gal (n=8): Ast 20 mg/kg (14) (oral) and D-gal 100 mg/kg (12) (i.p); After ten weeks of treatment, firstly, all groups were exposed to the passive avoidance (PA) task. After seven days of completion of PA the same group of mice has experienced the Contextual Fear Conditioning followed by collecting brain tissues to assay oxidative stress biomarkers.

RESULTS

Effects of VU0357017 on PA and CFC: After 24 and 48 hours of training, the RT value was decreased to 116.43 ± 2.62 s and 105.87 ± 3.58 s, respectively in mice that received D-gal injection. Contrarily, the RT was prominently elevated to 255.62 ± 14.11 s after 24 hours and 246.81 ± 14.38 s in case of 48 hours of training after administration of VU0357017 in D-gal mice. In the conditioning session, day 2A and 31A, the FR value was decreased to 42.5 ± 3.60 % and 35 ± 2.45 %, respectively after administration of D-gal. Intriguingly, FR increased to 67.60 ± 2.62 % (day 2A) and 62.18 ± 6.57 (day 31A) after treatment with VU0357017. In context and cued test, similar results were observed.

Effects of VU0357017 on oxidative stress biomarkers: The level of oxidative stress biomarkers was changed in D-gal mice. The MDA level was remarkably increased (115.9 ± 7.49 nmol/ml) whereas GSH and SOD level was significantly decreased (2.54 ± 0.23 μ mol/mg and 10.85 ± 0.94 U/30s; respectively; $P < 0.0001$). However, the GSH and SOD levels were increased (11.62 ± 0.53 μ mol/mg and 30.89 ± 0.89 U/30s; respectively) whereas MDA was significantly decreased (31.34 ± 6.11 nmol/ml after administration of VU0357017 ($P < 0.0001$)).

DISCUSSION

In this study, the D-gal mice exhibited a low level of learning, whereas an improvement of learning was detected in mice treated with VU0357017. These results suggested that VU0357017 can potentially affect learning and memory-impaired by D-gal (Fig.1). The biochemical study revealed significant changes in oxidative biomarkers in D-gal treated mice, whereas the expressions of biomarkers were regulated after using VU0357017 (Fig.2), suggesting VU0357017 has the potential antioxidant properties. Other studies showed that M1mAChRs have antioxidant activity (15). Therefore, it could be stated that VU0357017 improves memory by increasing the amount of m1mAChRs via modulating the oxidative biomarkers in the brain. The probable underlying antioxidant mechanism is due to the stimulation of b-arrestin pathway (7,8) by inhibiting NADPH oxidase 4 (7), a key generator of ROS in the brain (16). A study on human cell line have shown an outstanding selectivity of VU0357017 towards the m1mAChR and is regarded as a novel approach for AD (7). However, there is a lack of evidence to find the advantages and propitious effects of VU0357017 on AD. Therefore, the results obtained from animal studies might be transformed in human cases in the treatment of AD.

INTRODUCTION/MOTIVATION

Intentionality is a basic component of understanding the minds and behaviors of others. In this regard, the temporal lobe (anterior temporal lobe, superior temporal sulcus, middle and superior temporal gyrus) and the precuneus and temporo-parietal junction constitute a “mentalizing” network^{1,2} that encodes intentionality. Within this network, the Superior Temporal Sulcus (STS) and regions surrounding it have been related to being especially involved in processing communicative intention for interactions by means of gaze (direct vs. averted) in social perception³⁻⁷. Approach intentionality has been linked with greater activation of posterior right Superior Temporal Sulcus (rSTS) than avoidance⁸. STS could be an area required for processing intentionality for social interactions. Regarding transcranial direct current stimulation (tDCS) effects on the STS and relationship-actions processing, Marrero et al.⁹ found a greater improvement in discriminability of approach sentences in a memorization task after applying anodal tDCS on the rSTS, compared to either sham or cathodal stimulation. However, the question whether the advantage of approach contents could start before memorization (as during sentence reading) remains open. The goal of this study has been to see whether improvement in information encoding could start during the reading process. Based on Marrero et al.⁹, we hypothesized anodal tDCS would produce a greater improvement for approach sentences. Moreover, we explored whether an effect of tDCS on reading speed could be moderated by behavioral activation system (BAS, approach trait) and behavioral inhibition system (BIS, avoid-

ance trait)¹⁰. Low approach^{11,12} has been found as benefitting from anodal stimulation, but high avoidance trait has been shown to disturb attentional allocation¹³ in previous research. Hence, we would expect participant with high BAS and high BIS traits to be less capable of taking advantage of extra processing resources probably provided by anodal tDCS for the reading task. Therefore, we predicted a poorer reading improvement in approach as well as in avoidance sentences in high compared to low-BAS and BIS participants.

METHODS

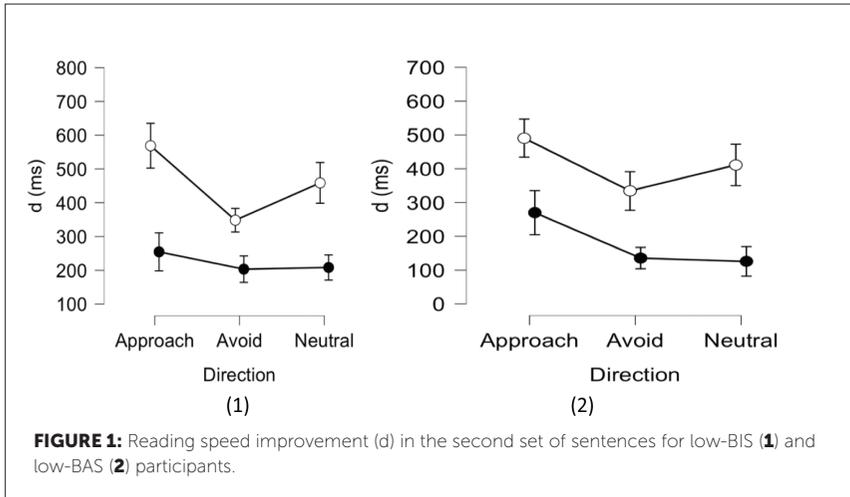

62 healthy right-handed students (54 females $M = 19,95$, $SD = 2,33$) voluntarily participated in the experiment. All participants provided informed consent. Inclusion criteria included: being right-handed according to the Edinburgh Handedness Inventory¹⁴. Exclusion criteria were suffering from epilepsy (or having close relatives affected), migraine, brain damage, cardiac, neurological or psychiatric disease. 31 participants were assigned to the anodal condition and 31 to the sham condition. The behavioral inhibition system (BIS) and behavioral activation system (BAS) scales were measured by the scales of Carver & White¹⁵. The difference between anodal and sham groups relied on stimulation duration: anodal-tDCS participants received stimulation for 20 minutes at 2 mA plus 15 s for fade in and 15 s for fade out, as the sham group did for only 15 s plus 15 s for fade in and 15 s for fade out as well. Participants were given one list before receiving tDCS (pre-test) and the other list after tDCS (post-test). Participants were randomly assigned to one of the four sets of sentences resulting from the counterbalance. Sentences were randomly presented to the participants in each of the counterbalanced sets. At the start of the experiment, participants were given seven sentences to practice. Then, they were given 60 sentences, 20 for each direction (Approach, Avoidance, Neutral). Sentences presentation was segmented (see Table 1). Each segment was displayed till the participant pressed the corresponding button. After 750 ms a new sentence appeared. Sixteen sentences were followed by a yes-no question on the content just read. Feedback on correctness and time required for it was given. These questions were aimed at keeping the attention of participants on reading comprehension.

Table 1: Examples of sentences with questions

Sentence	Direction	Question Example	Correct Answer
Pedro/aceptó a Rosa/ en Whatshapp (Pedro/accepted Rosa/ in Whatsapp)	Approach	¿Dice que Pedro aceptó a Rosa en Whatshapp? (Is it stated that Pedro accepted Rosa in Whatshapp?)	Yes
Pedro/bloqueó a Rosa/en Whatshapp (Pedro/blocked Rosa/ in Whatshapp)	Avoidance	¿Dice que Pedro aceptó a Rosa en Whatshapp? (Is it stated that Pedro accepted Rosa in Whatshapp?)	No
Verónica/dedujo el precio/del abrigo (Verónica/deduced the price/of the coat)	Neutral	¿Dice que Verónica dedujo el precio del abrigo? (Is it stated that Verónica deduced the price of the coat?)	Yes

RESULTS AND DISCUSSION

Two 3 X 2 mixed Two-Way ANOVAs were performed with Direction (Approach, Avoidance, Neutral) as a within-subjects and Stimulation (anodal, sham) as a between-subjects factor. The dependent variable (d) was the difference between time required to read both the second and third segments before and after the Stimulation condition (anodal or sham). Latency to answer questions after neutral sentences was considered as covariate. Anodal tDCS was able to enhance reading speed for all the three types of sentences ($F(1, 58) = 4.174, p < .05, \eta p^2 = .068$). No interaction effect between Stimulation and Direction was found.

Significant effect of anodal tDCS was found in low-BIS (avoidance/anxiety, $F(1,19) = 8.502, p < .01, \eta p^2 = .321$) participants and in low-BAS (approach/impulsivity, Stimulation, $F(1, 19) = 6.53, p = .02, \eta p^2 = .205$). Anodal tDCS enhance reading speed more for approach than avoidance sentences in low-BIS participants, $F(2,19) = 3.181, p = .067, \eta p^2 = .272$, (Figure 1).

In conclusion, anodal tDCS had no effect on reading approach content as we predicted but an overall effect on reading speed. However, affective traits have emerged as a modulator for tDCS effects. As we hypothesized, high levels in BIS/BAS traits predicted a poorer benefit from anodal tDCS. In contrast, low level BIS/BAS traits see, to be benefited from tDCS. More gender-balanced and older groups are needed. This may be interpreted as interference of personality traits as in previous research^{17,18}. Since the reading task was somewhat passive, a recognition task after reading is suggested to find tDCS improvement in information encoding.

ACKNOWLEDGEMENTS

INTRODUCTION/MOTIVATION

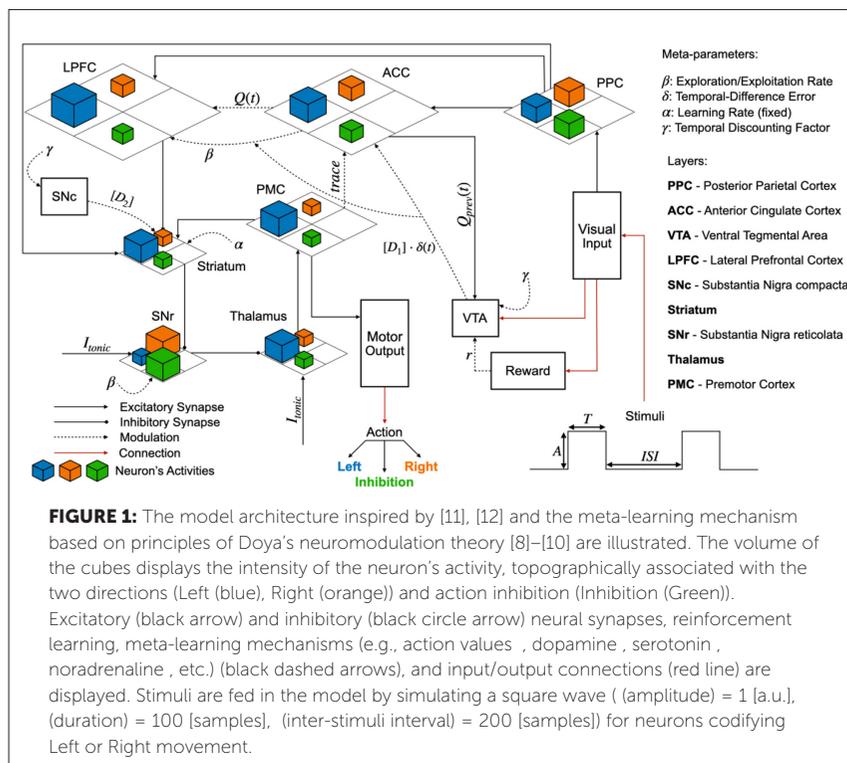

Modern artificial agents demonstrate well-established performance in terms of accuracy, speed, and reliability in operating on single task instances after the exposure of a long stationary learning. However, they might exhibit worse performance in non-deterministic environments, i.e., human real-case applications characterized by sources of uncertainty and variability such as unpredictable cues and constraints [1], [2]. Meta-learning, also known as “learning-to-learn”, applied to reinforcement learning may empower the design of flexible control algorithms, where an outer learning system progressively adjusts the operation of an inner learning system [3]–[5]. This approach could lead to practical learning optimization benefits, such as the reducing of the explicit hand-tuning of the hyperparameters of the learning schema and the generalization error [6], [7].

METHODS

Our work inherits the meta-learning principles in the neuromodulation theory proposed by Doya [8]–[10] and the neural architecture developed by Khamassi and colleagues [11], [12] for agent-environment interaction. The neuromodulation theory propounds a direct equivalence between the dynamics of the four major neurotransmitters (e.g., acetylcholine, serotonin, dopamine, and noradrenaline) and the computational role of the hyperparameters which shape the meta-learning processes.

In this brain-inspired meta-learning framework for inhibition cognitive control we included meta-learner representations of the distributed learning

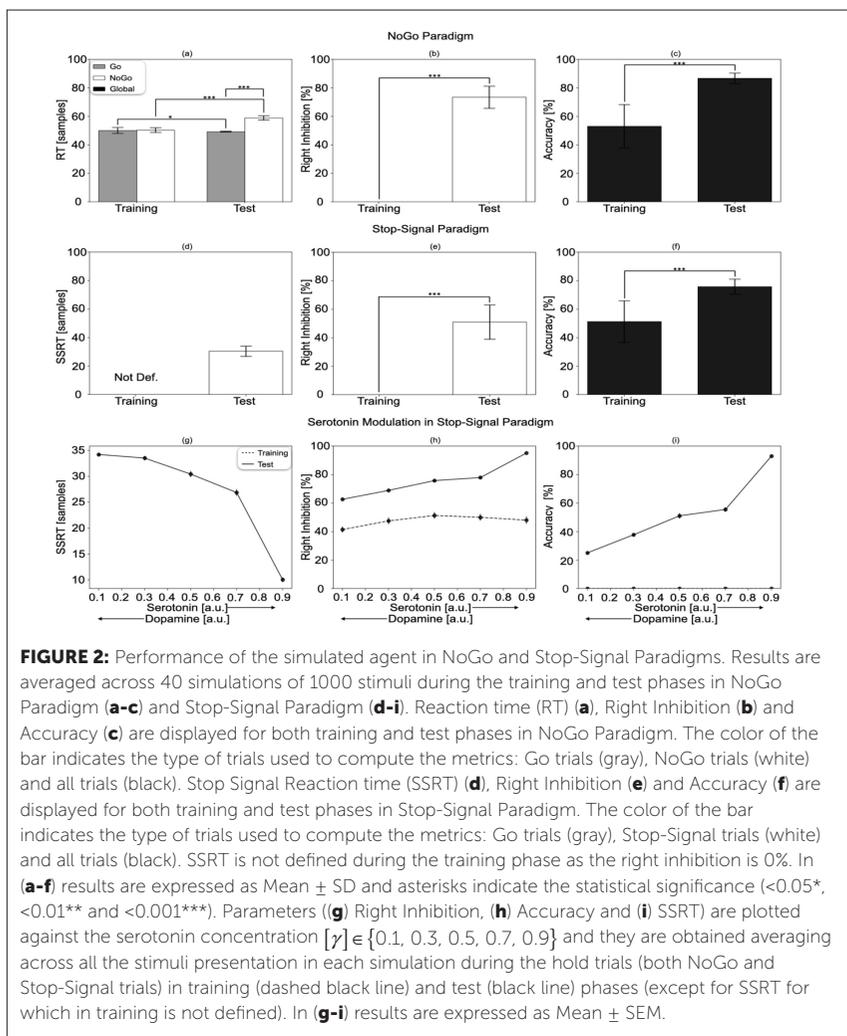

systems in the human brain ,e.g., cortical areas such as the prefrontal cortex (e.g., Posterior Parietal Cortex (PPC), Anterior Cingulate Cortex (ACC), Ventral Tegmental Area (VTA), Lateral Prefrontal Cortex (LPFC), Premotor Cortex (PMC)) and subcortical regions such as basal ganglia circuitry (e.g., Striatum, Substantia Nigra reticulata (SNr), Thalamus, Substantia Nigra compacta (SNc)) (Figure 1). Each layer is composed of three firing rate neurons (the output of the differential equation of each neuron is mapped from 0 to 1 with a sigmoid activation function) that topographically codify different space regions [13]; we used two neurons to encode two different opposite directions, e.g., left and right, and one neuron to encode the action inhibition [14]–[16]. The connection between neurons is only inter-layers (i.e., no intra-layer recurrent connections) mediated by one-to-one excitatory or inhibitory synapses [17] The visual perception and the external reward modules regulate how

the agent interacts with the environment and the output module delivers the corresponded motor commands of the selected action. We formalized brain-inspired meta-learning hyperparameters optimization rules, mimicking explicitly the dynamics and mutual interaction of the major neurotransmitters in the brain. Briefly, (i) dopamine receptors D_1 modulate the noradrenergic system (i.e. exploration/exploitation rate) with an inverse linear function that relates dopamine to the entropy of the probability distribution of the actions [18], (ii) dopamine receptors D_2 tune the striatum neuron's excitability [19], and (iii) serotonin regulates the overall dopamine release and the reward temporal scale [20], [21]. The artificial agent was tested in two different well-described in literature conflictual tasks that involve different types of action inhibition [22], [23]: action restraint in NoGo Paradigm and action cancellation in Stop-Signal Paradigm. In the former, we evaluated the ability to withdraw a not-yet-initiated action from responding by the appearance of a hold signal before the movement execution. In the latter, we investigated the ability to cancel an initiated response triggering an unpredictable hold signal after a range of delays from the action onset.

RESULTS AND DISCUSSION

The artificial agent, after the training session, learned how to adjust successfully its hyperparameters (e.g., driving the system towards exploitation regimes) in response to the appearance of the hold signal in both paradigms, and hence, showing a proper encoding of the action inhibition command (Figure 2). In particular, both right inhibition and global accuracy increased significantly during the test phase in NoGo Paradigm (accuracy, training: $53.10 \pm 15.43\%$ vs test: $86.74 \pm 3.68\%$, t-test, p-value < 0.001; right inhibition, training: 0% vs test: $73.48 \pm 7.86\%$, t-test, p-value < 0.001) and in Stop-Signal Paradigm (accuracy, training: $51.32 \pm 14.78\%$ vs test: $75.78 \pm 5.38\%$, t-test, p-value < 0.001; right inhibition: training: 0% vs test: $51.06 \pm 12.22\%$, t-test, p-value < 0.001). Finally, considering the Stop-Signal Paradigm, high serotonergic concentration acting on the dopamine release led to behavioral effects as such it shifted of the agent's behavior towards non-impulsive regimes, e.g., shorter reaction time and higher right inhibition as well as a reduction in the Stop Signal Reaction time, i.e., the latency of the cancellation process.

In previous works Khamassi and colleagues [11], [12] implemented a brain-inspired meta-learning hyperparameter optimization framework for reinforcement learning by linking the exploration/exploitation meta-parameter with the activity of two types of neurons [24], [25] (i.e., correct and error neurons) that react to positive and negative temporal difference error, respectively. The model was tested both in silico and in a humanoid

robot (i-Cub) in two problem solving tasks where environmental uncertainties are included either changing the cue or by cheating.

In the framework of the Cyber Rodent project [26], Doya e Uchibe used genetic algorithms to investigate the underlying mechanisms of self-reproduction, self-preservation as well as foraging in artificial agents [26]–[28] This evolutionary approach was adopted to co-evolve the meta-parameters (e.g., exploitation/exploration rate, learning rate and temporal discounting factor) in synergy with shaping reward, accelerating significantly the learning curve in foraging [29] and mating [30]. Lowe & Ziemke [31] used genetic algorithms to investigate meta-learned exploration and planning in a multi-episode two-armed bandit navigation problem under different representations (e.g., absence/presence) of external rewards and punishments.

We demonstrated that brain-inspired meta-learning rules may pave the way of the design of cognitive control architectures for artificial agents that achieve more flexible and accurate behavior when conflictual inhibitory signals are present in the non-deterministic environment.

INTRODUCTION/MOTIVATION

EBRAINS [1] comprises more than 130 European research organizations, each with a large number of scientists, programmers, and technical coordinators. Developing, operating, and using an immense infrastructure such as EBRAINS is a complex task that bears the risk of an individual scientist getting lost in details. The Scientific Liaison Unit (SLU) was founded to provide a helping hand in navigating the complexity of EBRAINS services [2] and science [3]. This work details the structured methodology the SLU uses to guide its activities. The method creates a shared understanding of the research plans of the scientists and the associated technical requirements for the engineers. Secondly, it facilitates the identification of major scientific needs, which serve as a precious source for defining the future direction of tool and service development in EBRAINS.

METHODS

Here we present the process we followed to develop a technique that describes scientific research as standardized requirements that conduces to a workflow compatible with EBRAINS infrastructure.

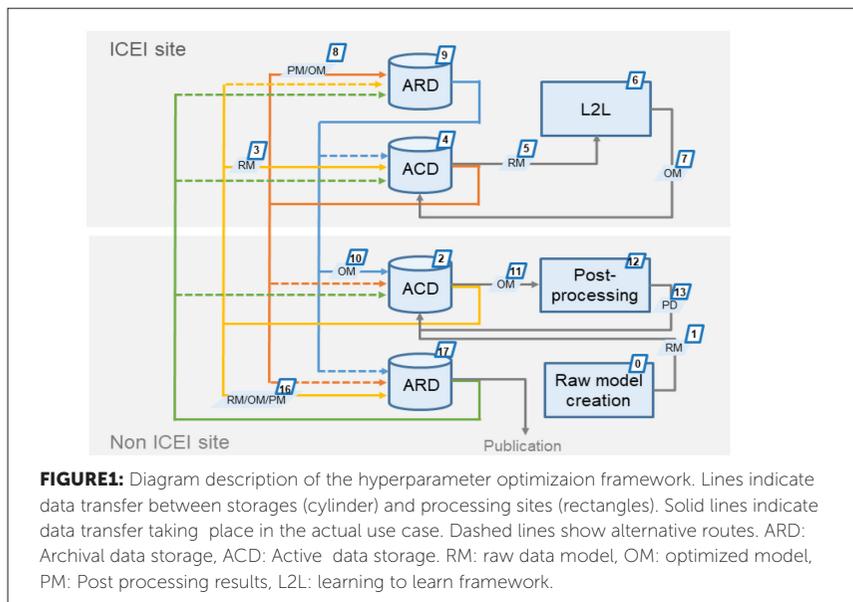

Also, here is clarified how this process of gathering requirements, can be applied to different types of research, and how it can help in similar cases to transform the actual state of research into compatible description workflows able to be integrated as a part of EBRAINS and how we designed tools to

optimize this process. *To exemplify we present showcases models and how the evolution of the used tools in their research.*

As a key tool, we introduce a descriptive template [4,5] that guides the scientist through a couple of steps: from a scientific description of her/his science case at the beginning, followed by a progressively technical presentation of it. The technical representation also includes a diagram with symbols organized according to specific rules that allow us to identify commonalities between different scientific cases and infer major scientific needs.

RESULTS AND DISCUSSION

Based on an example of the hyper-parameter optimization framework ([6], L2L in Fig.1) we demonstrate how the structure of the document leads the reader from a scientific description into technical requirement analysis. In this particular case, the technical requirement analysis focuses on different types of data transfer needed for this workflow e.g. data needs to be transferred from the super-compute site (ICEI site) in which the hyper-parameter optimization

takes place, to another site (e.g. your computer) in which the analysis of the result is carried out. Based on such a requirement analysis, potential project challenges, as well as opportunities for extensions and interaction, are identified early on.

This work gives an overview of the different areas of responsibility that the SLU has. In particular, it explains our strategies for identifying and prioritizing the needs of the scientific community and their formulation into technical requirements based on scientific cases in a systematic and standardized way.
