ABSTRACT

Mathematical operations are cognitive actions we take to calculate relations among numbers. Arithmetic operations, addition, subtraction, multiplication, and division are elemental in education. Addition is the first one taught in school and is most popular in functional magnetic resonance imaging (fMRI) studies. Division, typically taught last is least studied with fMRI. fMRI meta-analyses show that arithmetic operations activate brain areas in parietal, cingulate and insular cortices for children and adults. Critically, no meta-analysis examines concordance across brain correlates of separate arithmetic operations in children and adults. We review and examine using quantitative meta-analyses data from fMRI articles that report brain coordinates separately for addition, subtraction, multiplication, and division in children and adults. Results show that arithmetic operations elicit common areas of concordance in fronto-parietal and cingulo-opercular networks in adults and children. Between operations differences are observed primarily for adults. Interestingly, higher within-group concordance, expressed in activation likelihood estimates, is found in brain areas associated with the cingulo-opercular network rather than the fronto-parietal network in children, areas also common between adults and children. Findings are discussed in relation to constructivist cognitive theory and practical directions for future research.

1. Introduction

Children typically start elementary school with a basic understanding of numbers. In the next four years of schooling, they learn to add, subtract, multiply and divide, usually in that order. Many behavioral studies examine the mechanisms of learning mathematical operations (e.g., Lemaire and Siegler, 1995; Barrouillet et al., 2008), as they form the foundations for future academic performance (Shalev et al., 2005; Watts et al., 2014). Mathematical operations encompass a broader range of operations beyond basic arithmetic. Basic arithmetic operations involve addition, subtraction, multiplication, and division. Many functional Magnetic Resonance Imaging (fMRI) studies examine the brain correlates of mathematical processes such as numerical cognition in adults (Arsalidou and Taylor, 2011; Pollack and Ashby, 2018; Hawes et al., 2019; Sokolowski et al., 2023 for meta-analyses) and children (Pollack and Ashby, 2018; Arsalidou et al., 2018 for meta-analyses). Some of these meta-analyses examine the brain correlates of

arithmetic operations in adults, identifying concordance in prefrontal, parietal, cingulate and insular cortices (Arsalidou and Taylor, 2011; Pollack and Ashby, 2018; Hawes et al., 2019; Sokolowski et al., 2023). Meta-analyses of arithmetic operations in children show activation in parietal, cingulate and insular cortices, but not prefrontal cortices (Arsalidou et al., 2018; Pollack and Ashby, 2018). Critically, no review or meta-analysis to date examines concordance of separate arithmetic operations in children. As different arithmetic operations are said to rely on different strategies (e.g., addition and multiplication on retrieval, and subtraction on procedural; Grabner and De Smedt, 2011), it may be reasonable to expect that arithmetic operations may have some differences in brain representation. However, developmental cognitive theory suggest that learning relies on effortful attentional processes that can be applied during problem solving regardless of operations, and brain representation should be comparable when attentional requirements are comparable (Pascual-Leone, 1970; Agostino et al., 2010; Pascual-Leone et al., 2010). The current paper systematically reviews the adult and

children fMRI literature on arithmetic operations and maps concordant brain areas across eligible articles using quantitative meta-analyses.

The four adult-focused meta-analyses generally reveal a set of concordant regions in parietal, prefrontal, cingulate and insular cortices ([Arsalidou and Taylor, 2011](#); [Pollack and Ashby, 2018](#); [Hawes et al., 2019](#); [Sokolowski et al., 2023](#)). Children-focused fMRI work is less extensive. A review by [Peters and De Smedt \(2018\)](#) proposes that mathematical cognition in children implicates parietal, and temporal brain areas. Some suggest that prefrontal cortical activity exhibits a comparatively reduced magnitude when directly contrasted with that of adults, as highlighted in previous studies ([Davis et al., 2009](#); [Kucian et al., 2008](#)). Notably, two quantitatively meta-analyses that explore fMRI data from studies that examined brain responses to arithmetic

operations in children identify cingulate, insular and parietal cortices, but not prefrontal and temporal regions ([Pollack and Ashby, 2018](#); [Arsalidou et al., 2018](#)). Specifically, Pollack and Ashby report concordance in the left superior frontal gyrus (Brodmann area (BA) 6), right medial frontal gyrus (BA 8), cingulate gyrus (BA 32), and the right insula (BA 13). [Arsalidou et al. \(2018\)](#), in addition to the aforementioned areas in cingulate and insular cortices, report concordance in the parietal cortex. Specifically, left precuneus (BA 19) and inferior parietal lobule (BA 40), encompassing parts of the inferior parietal sulcus and angular gyrus (BA 39), alongside the right precuneus (BA 7).

One early adult meta-analysis examined separately concordance of addition, subtraction and multiplication ([Arsalidou and Taylor, 2011](#)). Specifically, addition tasks elicit concordant activation in visual areas,

parietal regions, frontal and prefrontal cortices, bilateral thalamus, right insula (BA 13), right claustrum, and bilateral cerebellum. Similarly, solving subtraction problems is linked to occipito-temporal visual regions, parietal areas, frontal and prefrontal regions, with additional activations observed in bilateral insula (BA 13) and right cerebellum. For multiplication tasks, activity is observed in occipito-temporal visual regions, parietal areas, temporal regions, frontal and prefrontal regions. Furthermore, consistent activations are seen in bilateral cingulate gyri (BA 32), bilateral thalamus, left claustrum, right insula, right caudate body, and right cerebellum across different studies.

This current report will be the first to examine concordance of separate arithmetic operations in children in comparison with adults, as the question remains whether the same brain regions are involved in solving tasks related to fundamental arithmetic operations in children and adults. Theoretically, it is expected that concordance in children will favor the insula and cingulate related to affective factors such as motivation and to a lesser extent the cognitive network that includes prefrontal and parietal regions (Arsalidou and Pascual-Leone, 2016). We do not anticipate differences among arithmetic operations.

2. Method

2.1. Literature review

PRISMA guidelines were used to document the steps taken for the systematic review and meta-analyses (Page et al., 2021). PubMed was searched using terms: fMRI and arithmetic, fMRI and calculations, fMRI and math, fMRI and addition/subtraction/multiplication/division in June 2023, searching all previous years. The search yielded a total of 1032, which resulted into 641 after duplicates were removed. Details for searches and steps taken for article eligibility are illustrated on Fig. 1.

2.2. Article eligibility criteria

Articles were subjected to two sets of inclusion/exclusion criteria. The initial stage of the screening process defined eligible the articles that (a) use fMRI, (b) present whole-brain group analyses accompanied by stereotactic coordinates expressed in either Talairach/Tournoux or Montreal Neurological Institute (MNI) space, (c) employ a minimum of one of the subsequent tasks: addition, subtraction, multiplication, division, (d) publish in the English language, (e) present number stimuli to participants in digits, words or had a symbolic designation, and (f) include a group of healthy children (up to mean age of 14 years) or adults (> 18 years). The second stage involved identifying eligible contrasts, by considering arithmetic operation used, types of statistical analyses conducted, and eligible contrasts (i.e., experiments). Eligible experiments were subtraction contrasts (e.g., task > control) rather than correlational analyses or multivariate analyses.

Contrasts (i.e., experiments) were systematically categorized according to the specific category of arithmetic operation for children (Table 1) and for adults (Table 2). Articles that reported results of mixed arithmetic operations (e.g., 3+2–4) or other complex mathematical operations (e.g., integration), were not considered. Inclusion criteria for addition, subtraction, and multiplication maps (division did not yield sufficient experiments: Fig. 1) were meticulously outlined as follows. Although we did not employ a behavioral performance criterion, we did verify that fMRI contrasts that involve tasks of different difficulty were expressed also in behavioral performance. That is, to include contrast Math task Hard > Math task Easy in the corresponding map, it was necessary to ensure that task Math task Easy was easier than task Math task Hard by way of differences expressed in behavioral scores, such as reaction time, accuracy, or performance efficiency.

The addition category included the following contrast types: (a) Addition > Control Task, (b) Addition Hard > Addition Easy, (c)

Addition > Baseline, (d) Addition > Rest, (e) Addition > Fixation, (f) Addition before train > Addition after train. The Subtraction category included the following contrast types: (a) Subtraction > Control Task, (b) Subtraction Hard > Subtraction Easy, (c) Subtraction > Baseline, (d) Subtraction > Rest, (e) Subtraction > Fixation, (f) Subtraction before train > Subtraction after train. The Multiplication problem maps included the following contrast types: (a) Multiplication > Control Task, (b) Multiplication Hard > Multiplication Easy, (c) Multiplication > Baseline, (d) Multiplication > Rest, (e) Multiplication > Fixation, (f) Multiplication before train > Multiplication after train. The Division category comprised four articles within the adults' group (Fehr et al., 2007; Wood et al., 2008; Ischebeck et al., 2009; Rosenberg-Lee et al., 2011), whereas no articles were available for the children's group.

2.3. Activation likelihood estimation (ALE)

We used open-source software GingerALE (version 3.0.2; www.gingerale.org/).

GingerALE (brainmap.org/ale/). ALE is a coordinate-based meta-analytical method that combines data from multiple experiments investigating a common cognitive phenomenon (Turkeltaub et al., 2002; 2012; Eickhoff et al., 2016; 2017). This method quantifies the probability of continuous activation in a specific voxel across multiple sources within a predefined category or group and enables the examination brain regions associated with distinct functions of interest. To have sufficient power to detect moderate effect sizes categories of interest should have 17 or more experiments (i.e., contrasts; Eickhoff et al., 2017). Because of lack of sufficient experiments, we could not perform meta-analyses on the category of division. To standardize all coordinates to a common coordinate system, the built-in Lancaster transform (icbm2tal) was employed to convert all MNI coordinates to Talairach space. To visualize the results obtained from the ALE maps, we utilized the AFNI software (version AFNI for Mac OS versions 10.9–15; Cox, 1996).

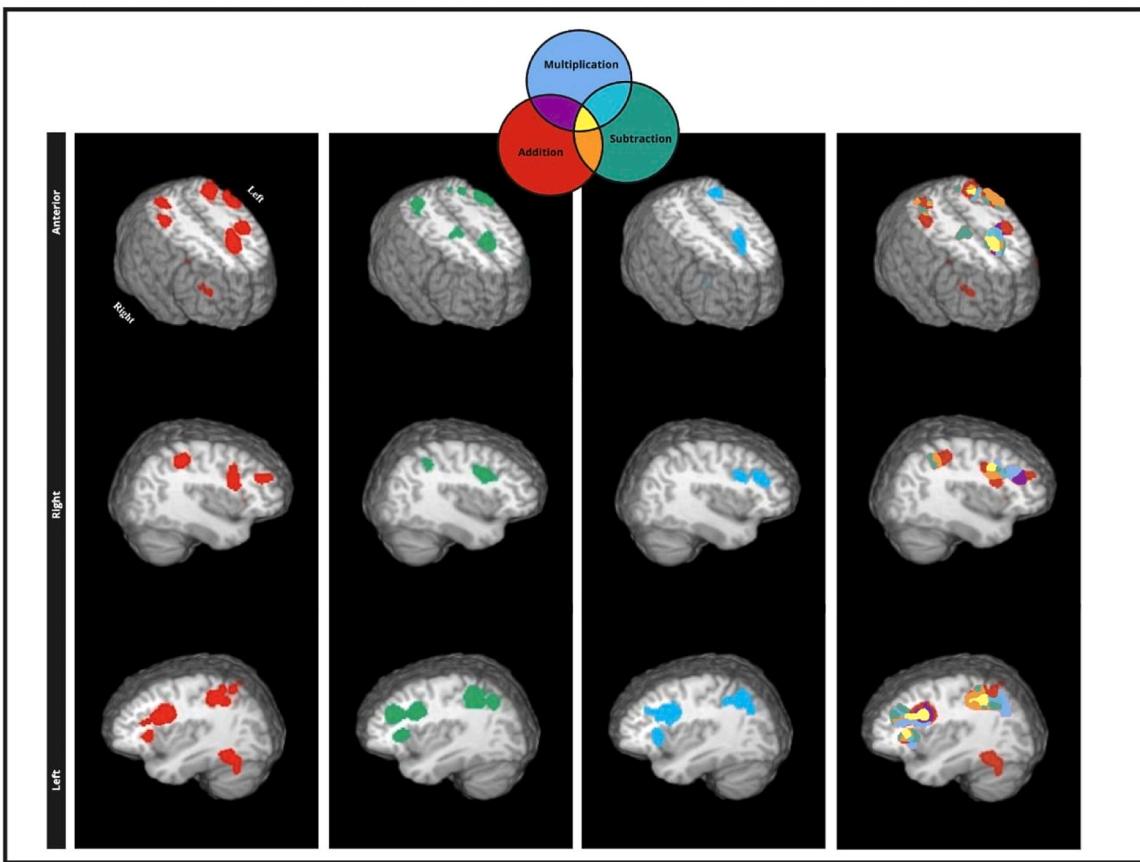

Fig. 2. Single dataset ALE maps of addition, subtraction, multiplication, and a visual overlay of all operations (addition, subtraction, multiplications) in adults. These maps were generated in AFNI using a cluster-level correction of 0.05 with 1000 threshold permutations and a cluster-forming threshold of $p < 0.001$. Coordinates in Talairach space and brain labels are in Table 3.

2.4. Single dataset analyses

Single dataset ALE meta-analyses were performed for adults for arithmetic operations of addition, subtraction, and multiplication. Single datasets for children, ALE meta-analyses were performed for addition, subtraction, and multiplication. We note that multiplication had 11 experiments, however, we decided to analyze this category as it may be indicative of trends. All single dataset ALE analyses were subjected to a cluster-level correction for controlling multiple comparisons of $p = 0.05$, utilizing a cluster-forming threshold of $p < 0.001$ (Eickhoff et al., 2012).

2.5. Conjunction and contrast analyses

GingerALE was employed to conduct conjunction and contrast analyses in order to ascertain common and distinct areas across arithmetic operation in adults and children. For these analyses, an uncorrected threshold of $p < 0.001$ was utilized, with 5000 threshold permutations and a minimum volume criterion of 50 mm^3 , as it was on images that already surpassed the rigorous thresholds of cluster-level correction of $p = 0.05$ and cluster-forming threshold of $p = 0.001$ employed in the creation of the single-file maps (Eickhoff et al., 2012). The same threshold parameters were employed for conjunction and contrast analyses conducted between the age groups (i.e., children vs adults) for each arithmetic operation. Notably, GingerALE software allow comparisons (conjunction and contrast) between two datasets at a time, thus we directly compared arithmetic operations within each age groups (e.g., children addition vs children subtraction; adult addition vs adult subtraction) and each arithmetic operation between groups (e.g., addition adults vs addition children).

3. Results

Our sample consisted of adults (Addition, $n = 376$, Males = 151, 25.8 ± 4.93 years-old; Subtraction, $n = 424$, Males = 208, 28.18 ± 6.62 years-old; Multiplication, $n = 424$, Males = 247, 28.18 ± 6.62 years-old) and children (Addition, $n = 653$, Males = 253, 9.43 ± 1.7 years-old; Subtraction, $n = 268$, Males = 110, 10.09 ± 1.43 years old; Multiplication, $n = 266$, Males = 118, 10.73 ± 0.85 years-old).

3.1. Single dataset meta-analyses

Brain areas concordant across experiments that examine arithmetic operations: addition, subtraction, and multiplication for children and adults are illustrated on Figs. 2 and 3. Table 3 list the corresponding coordinates, brain labels and statistical parameters.

3.2. Conjunction and contrast meta-analyses

Analyses showing common (i.e., conjunction) and distinct (i.e., contrast) brain areas among arithmetic operations in adults and children are listed on Table 4 and Table 5, respectively.

Analyses showing common and distinct brain areas between adults and children are listed on Table 6. Although the conjunction of children and adults show the highest ALE scores in right insula and the left superior frontal gyrus (BA6; adjacent to the dorsal cingulate), the contrast analysis show that adults implicate more extensive set of areas that include prefrontal and temporal areas.

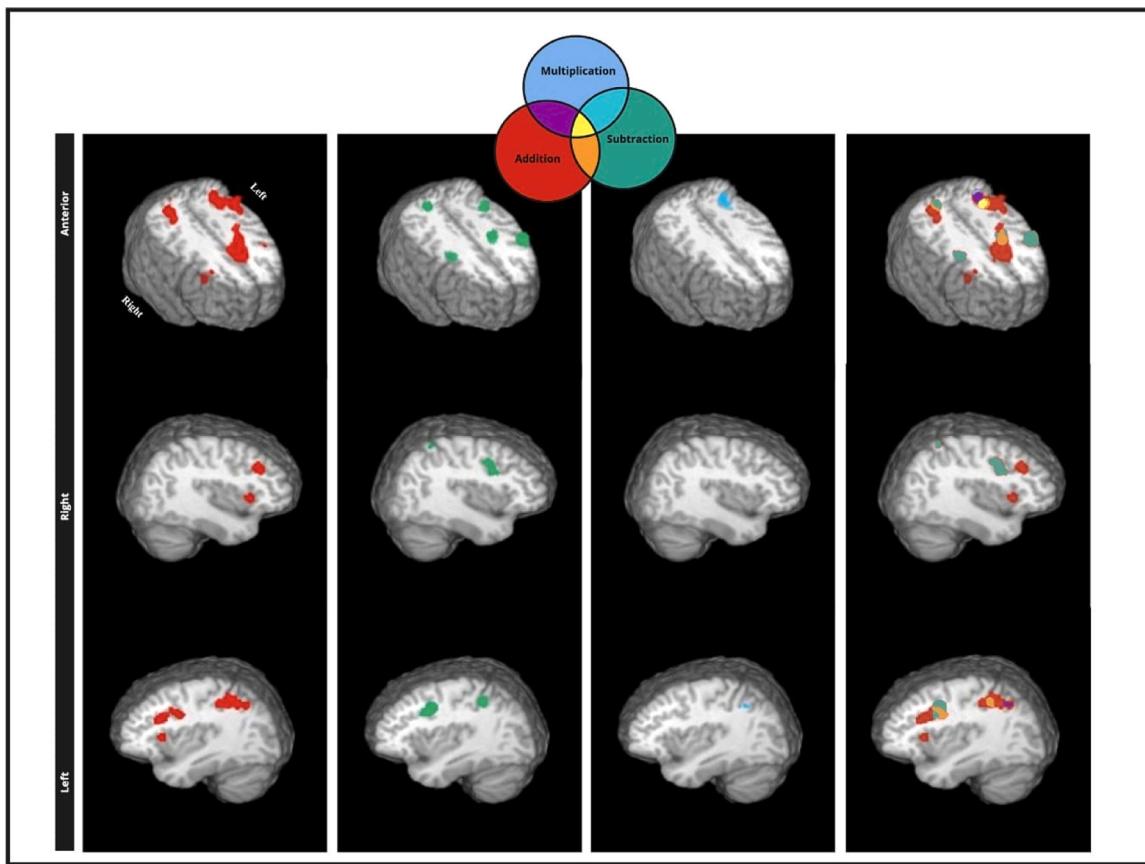

Fig. 3. Single dataset ALE maps of addition, subtraction, multiplication, and a visual overlay of all operations (addition, subtraction, multiplications) in children. These maps were generated in AFNI using a cluster-level correction of 0.05 with 1000 threshold permutations and a cluster-forming threshold of $p < 0.001$. Coordinates in Talairach space are reported in Table 3.

4. Discussion

Brain coordinates associated with separate arithmetic operations in adults and children were examined using systematic review and quantitative ALE meta-analyses. We highlight three key findings:

(a) Adults show concordance in a widespread set of brain regions when solving arithmetic operations in both hemispheres. Although brain areas are similar among arithmetic operations (e.g., parietal, insular and prefrontal regions) we note that they exhibit varied strength order in terms of ALE scores. For instance, the left superior frontal gyrus (BA 6) and right insula have the highest likelihood of being detected for addition, the right precuneus and left inferior frontal gyrus show the highest likelihood of being detected for subtraction, and for multiplication the top ALE scores are observed in the left inferior frontal gyrus and insula. Conjunction analyses revealed many clusters among arithmetic operations with the highest ALE scores in the left inferior frontal gyrus (BA 9) and parts of the parietal cortex, suggesting that implication of the fronto-parietal network is common for math problem solving in adults. Contrast analyses among operations show few significant differences in favor of subtraction in left middle frontal gyrus (BA 9) (subtraction > addition) and left middle frontal gyrus (BA 46) and bilateral parietal areas (BA 7, 39, 40; subtraction > multiplication); suggestive of the need of increased fronto-parietal resources for subtraction. Results point to the notion that common cognitive resources underlie mathematical problem solving, consistent with theoretical understanding of implementing general cognitive processes of mental attention or working memory (e.g.,

Pascual-Leone, 1970; Pascual-Leone and Johnson, 2021) and empirical research that points to a fronto-parietal network that also underlies processes of mental attention or working memory that are not specifically numeric (e.g., Owen et al., 2005; Wang et al., 2019; Yaple et al., 2021 for meta-analyses).

- (b) Like adults, children also activate a widespread set of regions in both hemispheres when solving arithmetic operations, that include areas in the fronto-parietal and cingulo-opercular networks, albeit areas in the cingulo-opercular network show the highest ALE scores. Specifically, the left insula and right claustrum (an area adjacent to the insula) showed the highest concordance for addition, the right precentral gyrus (BA 6; adjacent to the dorsal cingulate) and the left insula showed the highest concordance for subtraction; multiplication showed the highest concordance in the right cingulate gyrus (BA 32; dorsal cingulate) and left precuneus. Conjunction analyses revealed several statistically common regions among operations with the highest ALE scores in the insular cortex (BA 13), cingulate gyrus (BA 32), and inferior frontal gyrus (BA 9). No statistically significant differences among operations were observed, as expected. These results highlight that the cingulo-opercular network, a network that links the insula with the dorsal cingulate is key for solving arithmetic operations in children.
- (c) Conjunction analyses for children and adults show that the left BA 6, and the right insula receive the highest ALE scores among other clusters for both addition and subtraction, and the left precuneus for multiplication. Contrasts analyses between age groups showed no concordance for children over and above that of adults, however, adults showed increased concordance in prefrontal, parietal, and temporal cortices.

Overall, results converge in revealing that multiple brain areas are needed in mathematical cognition, albeit the extent of brain area involvement is in part modulated by age and less by operation. Two key networks observed in our analyses are the cingulo-opercular and the fronto-parietal networks. The fronto-parietal network comprises brain regions primarily involving the lateral prefrontal and posterior parietal cortices, including the dorsolateral prefrontal cortex and the inferior parietal lobule. This network is proposed to be involved in all sorts of cognitive processes such as mental attention, working memory and decision-making (Vincent et al., 2008; Arsalidou et al., 2013; Yaple et al., 2021). The cingulo-opercular network encompasses several interconnected brain regions predominantly in the anterior cingulate cortex the anterior insula and adjacent opercular regions (Dosenbach et al., 2007; Gratton et al., 2017). The dorsal cingulate involvement often extends to adjacent regions including superior and medial frontal gyri (BA 6). The cingulo-opercular areas are associated with various tasks that involve cognitive control (Stocco and Anderson, 2008; Sestieri et al., 2014; Aben et al., 2020; Goodman et al., 2020; Zacharopoulos et al., 2023) including mathematical problem solving (Arsalidou et al., 2018; Pollack and Ashby, 2018). The cingulo-opercular network often activates together with the fronto-parietal network.

Descriptive results from within group contrasts show that areas in the cingulo-opercular network mainly exhibit higher ALE scores (i.e., likelihood of being detected) than the fronto-parietal network in children. Descriptive results from within-group contrasts in adults primarily indicate higher ALE scores in areas of the fronto-parietal network. Statistical contrasts reveal regions of common concordance between children and adults in both fronto-parietal and cingulo-operculum regions. However, adults show significantly greater concordance than children in prefrontal, parietal, and temporal regions, but not cingulo-operculum regions. As the cingulo-opercular network favors affective functions (Servaas et al., 2015; Arsalidou and Pascual-Leone, 2016; Hung et al., 2018; van den Heuvel and de Wit, 2018) and the fronto-parietal network favors cognitive functions (Kaufmann et al., 2011; Qiao et al., 2020), the results seem to be in agreement with the notion that every cognitive action requires an affective motivation (Arsalidou and Pascual-Leone, 2016). In essence, the data suggest that mathematical problem solving requires both cognitive and affective processes for both children and adults, albeit adults show statistically more concordance in areas that support cognitive processes. We highlight empirical and theoretical links with past literature. We also provide maps in stereotaxic space for adults and children that can benefit future studies that examine addition, subtraction, and multiplication.

Arithmetic operations in adults engage a widespread set of areas in the fronto-parietal and cingulo-opercular networks, in agreement past meta-analyses (Arsalidou and Taylor, 2011; Pollack and Ashby, 2018; Hawes et al., 2019; Sokolowski et al., 2023). Although we did not except significant differences among arithmetic operations, we identified increased concordance for subtraction tasks for adults that show heightened engagement of the right inferior frontal gyrus and the left superior parietal cortex. The right inferior frontal gyrus is recognized for

its role in inhibitory control (Cai et al., 2014; Sebastian et al., 2016; Schroeder et al., 2020; Boen et al., 2022; Choo et al., 2022; Brown et al., 2023) and cognitive flexibility (Marklund and Persson, 2012; Rudebeck et al., 2013; Schaum et al., 2021; Sundby et al., 2021). As part of the lateral fronto-parietal network these areas play a key role in core cognitive resources that support mental attention (Arsalidou et al., 2013; Arsalidou and Pascual-Leone, 2016; Pascual-Leone and Johnson, 2021) and working memory (Rottschy et al., 2012; Yaple et al., 2021 for meta-analyses). The execution of subtractive operations typically requires regrouping and borrowing of numbers that may correspond to this increased involvement. Others have discussed unique cognitive demands and strategies intrinsic to each operation (Grabner and De Smedt, 2011). Addition and multiplication were proposed to be of automatic nature. Automatic calculations predominantly rely on rote memorization and factual retrieval, potentially accounting for the comparable brain activation patterns between addition and multiplication. Some also consider that math problem solving skills rely on core resources that change with development (Agostino et al., 2010; Arsalidou et al., 2018). Compared to addition and multiplication, subtraction entails more intricate processes, such as regrouping and borrowing, necessitating heightened cognitive control, and working memory (Campbell and Xue, 2001; Campbell, 2008). We did not anticipate differences among arithmetic operations because we assumed comparable cognitive demands among addition, subtraction, multiplication. However, subtraction problems in adults may have been more demanding in terms of processing steps, thus, the distinct brain areas observed for subtraction may reflect distinct cognitive demands associated with this operation in adults.

For children, all arithmetic operations engage brain areas in fronto-parietal and cingulo-opercular networks, albeit the cingulo-opercular areas generally show higher likelihood of being detected. Specifically, the insula (BA 13), claustrum, superior frontal gyrus (BA 6), and cingulate gyrus (BA 32) were among the regions with the highest ALE scores. These areas were also evident in the conjunction analyses among operations. The anterior insula is located deep within the lateral fissure and has been related with all sorts of affective and cognitive processes (Menon and Uddin, 2010; Duerden et al., 2013; Gasquoine, 2014; Uddin et al., 2017; Schimmelpfennig et al., 2023). The claustrum is a thin strip of cortex adjacent to the insula and is proposed to have a multimodal integrative role (Bennett and Baird, 2006) and as a primary region associated with consciousness (Goll et al., 2015). In mathematical cognition the insula was proposed to be a toggler between goal-directed and default-mode processes and the claustrum to have a role in motivated top-down processes (Arsalidou et al., 2018). As most neuro-imaging studies analyze brain correlates of individuals who actively engage in problem solving with satisfactory performance, the rationale behind this explanation becomes apparent. The superior frontal gyrus (BA 6) is adjacent to the dorsal cingulate gyrus and often activates in various studies of core cognitive processes such as working memory (Rottschy et al., 2012; Yaple et al., 2021 for meta-analyses), inhibitory control (Hung et al., 2018; Li et al., 2022 for meta-analyses), and

cognitive flexibility (Armbuster et al., 2012; Chen et al., 2014; Wengdiggensen and Beste, 2023). In mathematical cognition, the role of the dorsal cingulate has been linked to implementing cognitive goals (Arsalidou et al., 2018). This is consistent with the rational that children who do not adhere to their cognitive goal and solve the math problem correctly, their data are likely to be eliminated from analyses because the researchers cannot directly determine whether the response was given because the child was unable to do the task or unmotivated to do the task. Therefore, as part of the cingulo-opercular network, the insula and the dorsal cingulate, we propose that they have a generic role that

underlies mechanisms related motivated task engagement.

The lateral fronto-parietal network has been discussed extensively as part of the working memory network (Yaple et al., 2019; Emch et al., 2019 for meta-analyses) and other executive functions (Houdé et al., 2010; Desco et al., 2011; Ardila et al., 2017). In mathematics the role of fronto-parietal regions has been associated with the procedural manipulation of numerical quantities (Prado et al., 2014, Van Der Auwera et al., 2023). Specifically, reports suggest that the angular gyrus, supports the ability to retrieve arithmetic facts in both typically developing children and adults (Sokolowski et al., 2023b). In number and

calculation tasks, the inferior and middle frontal gyri have been associated with monitoring simple rules and more complex rules, respectively (Arsalidou et al., 2018).

Notably, as expected, we did not observe statistically significant differences among arithmetic operations in children. Considering that children included in the articles we analyzed were 9 and 10 years old on average for addition and subtraction and closer to 11 years old for multiplication, one could suggest that children's abilities in arithmetic operations greatly improve through learning during early school years (Entwistle and Alexander, 1989; Clements and Sarama, 2007; Rodic et al., 2018) and variability in brain response may be expressed in less detectable differences. The lack of differences in brain correlates among arithmetic operations may be also due to comparable experience across operation types (Evans et al., 2016; Brignoni-Pérez et al., 2021) as 9–10-year-olds should have had a couple of years of experience in addition and subtraction and 11-year-olds should have a couple of years of experience in multiplication. This is consistent with the theoretical proposal that children can comfortably solve arithmetic operations within the limits of their mental attentional capacity (Agostino et al., 2010; Pascual-Leone et al., 2010) and our analyses demonstrates the brain correlates of children that can inform this theoretical idea.

Compared to children, adults with an average age of about 27 years old have more extensive experience with all basic mathematical operations. Although conjunction analyses between children and adults shows common fronto-parietal and cingulo-opercular regions, confirming single dataset analyses, studies with adults showed statistically more concordance in prefrontal, parietal, and temporal regions than children. Specifically, contrasts between adults and children showed significant increase in concordance in the inferior frontal gyrus (BA 9, 44) and fusiform gyrus (BA 37) in the left hemisphere for addition, and left hemisphere angular gyrus (BA 39), precuneus (BA 19) and middle frontal gyrus (BA 9/46) for subtraction. Children did not show any concordance above and beyond brain areas implicated in math problem solving in adults. The inferior frontal gyrus, particularly BA 44 is acknowledged to be intricately associated with the region commonly referred to as the Broca area (Kulik et al., 2022). Broca's area retains its centrality in language processing; however, its role transcends mere language production, encompassing higher-order cognitive functions that pertain to working memory (Chein et al., 2002). The left fusiform gyrus often assumes a significant role in the recognition and

identification of alphabetical strings, facilitating their transmission to regions implicated in number processing and retrieval of arithmetic facts (Venkatraman et al., 2006). The left angular gyrus, whose spatial localization is associated with Wernicke's area known for its role in language comprehension (Binder, 2017; Jäncke et al., 2021), demonstrated an increased activation correlating with chronological age (Rivera et al., 2005). The observed outcome could potentially be attributed to the prevalence of language-based strategies employed by adults when engaging in mathematical problem-solving tasks (Kwon et al., 2002). Therefore, the activation differences between adults and children could reflect developmental changes in the organization and functionality of these brain regions over time. Moreover, the findings may suggest that certain cognitive strategies or approaches used by adults in the tasks are not yet fully established in children. Overall, concordance in these brain regions in adults and their absence in children provides valuable insights into the neural underpinnings of cognitive and mathematical processing during the analyzed tasks, highlighting the developmental differences between these two groups in terms of brain function and cognitive abilities.

5. Limitations

We note that fMRI meta-analyses in general cannot control for variability in statistical methodologies and thresholding approaches used by original studies. The present meta-analyses used peak coordinates reported by original peer-reviewed published studies that examine arithmetic operations in children and adults. We note two considerations for interpreting the results of the present meta-analyses. First, we did not control for task difficulty within each arithmetic operation which may have affected the participants' computational strategies, however, most articles used single digit numbers for addition and subtraction, and most articles use problems in the multiplication table. Second, we point out again that we only had 11 experiments with multiplication problems in children rather than a minimum of 17 experiments (Eickhoff et al., 2017), thus results related to children's multiplication tasks is underpowered.

6. Conclusion

We conducted a comprehensive investigation into brain activations

Table 6

Conjunction and contrast analyses: Comparing Addition, Subtraction, Multiplication between children and adults.

associated with separate mathematical operations in both children and adults. We identified several key findings that contribute to our understanding of the neural underpinnings of mathematical processing. Our within-group results revealed that children and adults show concordance in frontal-parietal and cingulo-opercular areas with children generally showing higher ALE scores in the later. Subtraction elicits significantly distinct concordance mainly of fronto-parietal regions, in adults, but not in children. Division remains an understudied operation and further research is needed. Theoretically, our results are consistent with general, constructive theories of cognitive development (e.g., [Pascual-Leone, 1970](#); [Pascual-Leone and Johnson, 2021](#)). The stereotaxic coordinate maps we provide serve as a benchmark for future research with neurodevelopmental disorders as well as for individuals exhibiting exceptional mathematical proficiency.
